A Priori v Post Hoc Testing

Macdonald [11] points out some of the problems with post hoc analyses, and offers as an example the P value one would ascribe to drawing a particular card from a standard deck of 52 playing cards. If the null hypothesis is that all 52 cards have the same chance ($1/52$) to be selected, and the alternative hypothesis is that the ace of spades will be selected with probability one, then observing the ace of spades would yield a P value of $1/52$. For a Bayesian perspective (see **Bayesian Statistics**) on a similar situation involving the order in which songs are played on a CD, see Sections 4.2 and 4.4 of [13]. Now then, with either cards or songs on a CD, if no alternative hypothesis is specified, then there is the problem of inherent multiplicity. Consider that regardless of what card is selected, or what song is played first, one could call it the target (alternative hypothesis) after-the-fact (post hoc), and then draw the proverbial bull's eye around it, quoting a P value of $1/52$ (or $1/12$ if there are 12 songs on the CD). We would have, then, a guarantee of a low P value (at least in the case of cards, or more so for a lottery), thereby violating the probabilistic interpretation that under the null hypothesis a P value should, in the continuous case, have a uniform distribution on the unit interval $[0,1]$. In any case, the P value should be less than any number k in the unit interval $[0,1]$, with probability no greater than k [8].

The same problem occurs when somebody finds that a given baseball team always wins on Tuesdays when they have a left-handed starting pitcher. What is the probability of such an occurrence? This question cannot even be properly formulated, let alone answered, without first specifying an appropriate probability model within which to embed this event [6]. Again, we have inherent multiplicity. How many other outcomes should we take to be as statistically significant as or more statistically significant than this one? To compute a valid P value, we need the null probability of all of these outcomes in the extreme region, and so we need both an enumeration of all of these outcomes and their ranking, based on the extent to which they contradict the null hypothesis [3, 10].

Inherent multiplicity is also at the heart of a potential controversy when an interim analysis is used, the null hypothesis is not rejected, the study continues to the final analysis, and the final P value is greater than the adjusted alpha level yet less than the overall alpha level (see **Sequential Testing**). For example, suppose that a maximum of five analyses are planned, and the overall alpha level is 0.05 two-sided, so that 1.96 would be used as the critical value for a single analysis. But with five analyses, the critical values might instead be $\{2.41, 2.41, 2.41, 2.41, 2.41\}$ if the Pocock sequential boundaries are used or $\{4.56, 3.23, 2.63, 2.28, 2.04\}$ if the O'Brien–Fleming sequential boundaries are used [9]. Now suppose that none of the first four tests result in early stopping, and the test statistic for the fifth analysis is 2.01. In fact, the test statistic might even assume the value 2.01 for each of the five analyses, and there would be no early stopping.

In such a case, one can lament that if only no penalty had been applied for the interim analysis, then the final results, or, indeed, the results of any of the other four analyses, would have attained statistical significance. And this is true, of course, but it represents a shift in the ranking of all possible outcomes. Prior to the study, it was decided that a highly significant early difference would have been treated as more important than a small difference at the end of the study. That is, an initial test statistic greater than 2.41 if the Pocock sequential boundaries are used, or an initial test statistic greater than 4.56 if the O'Brien–Fleming sequential boundaries are used, would carry more weight than a final test statistic of 1.96. Hence, the bet (for statistical significance) was placed on the large early difference, in the form of the interim analysis, but it turned out to be a losing bet, and, to make matters worse, the standard bet of 1.96 with one analysis would have been a winning bet. Yet, lamenting this regret is tantamount to requesting a refund on a losing lottery ticket. In fact, almost any time there is a choice of analyses, or test statistics, the P value will depend on this choice [4]. It is clear that again inherent multiplicity is at the heart of this issue.

Clearly, rejecting a prespecified hypotheses is more convincing than rejecting a post hoc hypotheses, even at the same alpha level. This suggests that the timing of the statement of the hypothesis could have implications for how much alpha is applied to the resulting analysis. In fact, it is difficult to

answer the questions ‘Where does alpha come from?’ and ‘How much alpha should be applied?’, but in trying to answer these questions, one may well suggest that the process of generating alpha requires a prespecified hypothesis [5]. Yet, this is not very satisfying because sometimes unexpected findings need to be explored. In fact, discarding these findings may be quite problematic itself [1]. For example, a confounder may present itself only after the data are in, or a key assumption underlying the validity of the planned analysis may be found to be violated. In theory, it would always be better to test the hypothesis on new data, rather than on the same data that suggested the hypothesis, but this is not always feasible, or always possible [1]. Fortunately, there are a variety of approaches to controlling the overall Type I error rate while allowing for flexibility in testing hypotheses that were suggested by the data. Two such approaches have already been mentioned, specifically the Pocock sequential boundaries and the O’Brien–Fleming sequential boundaries, which allow one to avoid having to select just one analysis time [9].

In the context of the **analysis of variance**, Fisher’s least significant difference (LSD) can be used to control the overall Type I error rate when arbitrary pairwise comparisons are desired (*see Multiple Comparison Procedures*). The approach is based on operating in protected mode, so that these pairwise comparisons occur only if an overall equality null hypothesis is first rejected (*see Multiple Testing*). Of course, the overall Type I error rate that is being protected is the one that applies to the global null hypothesis that all means are the same. This may offer little consolation if one mean is very large, another is very small, and, because of these two, all other means can be compared without adjustment (*see Multiple Testing*). The Scheffe method offers simultaneous inference, as in any linear combination of means can be tested. Clearly, this generalizes the pairwise comparisons that correspond to pairwise comparisons of means.

Another area in which post hoc issues arise is the selection of the primary outcome measure. Sometimes, there are various outcome measures, or end points, to be considered. For example, an intervention may be used in hopes of reducing childhood smoking, as well as drug use and crime. It may not be clear at the beginning of the study which of these outcome measures will give the best chance to

demonstrate statistical significance. In such a case, it can be difficult to select one outcome measure to serve as the primary outcome measure. Sometimes, however, the outcome measures are fusible [4], and, in this case, this decision becomes much easier. To clarify, suppose that there are two candidate outcome measures, say response and complete response (however these are defined in the context in question). Furthermore, suppose that a complete response also implies a response, so that each subject can be classified as a nonresponder, a partial responder, or a complete responder.

In this case, the two outcome measures are fusible, and actually represent different cut points of the same underlying ordinal outcome measure [4]. By specifying neither component outcome measure, but rather the information-preserving composite end point (IPCE), as the primary outcome measure, one avoids having to select one or the other, and can find legitimate significance if either outcome measure shows significance. The IPCE is simply the underlying ordinal outcome measure that contains each component outcome measure as a binary sub-endpoint. Clearly, using the IPCE can be cast as a method for allowing post hoc testing, because it obviates the need to prospectively select one outcome measure or the other as the primary one. Suppose, for example, that two key outcome measures are response (defined as a certain magnitude of benefit) and complete response (defined as a somewhat higher magnitude of benefit, but on the same scale). If one outcome measure needs to be selected as the primary one, then it may be unclear which one to select. Yet, because both outcome measures are measured on the same scale, this decision need not be addressed, because one could fuse the two outcome measures together into a single trichotomous outcome measure, as in Table 1.

Even when one recognizes that an outcome measure is ordinal, and not binary, there may still be a desire to analyze this outcome measure as if it were binary by dichotomizing it. Of course, there is a different binary sub-endpoint for each cut point of

Table 1 Hypothetical data set #1

	No response	Partial response	Complete response
Control	10	10	10
Active	10	0	20

the original ordinal outcome measure. In the previous paragraph, for example, one could analyze the binary response outcome measure (20/30 in the control group vs 20/30 in the active group in the fictitious data in Table 1), or one could analyze the binary complete response outcome measure (10/30 in the control group vs 20/30 in the active group in the fictitious data in Table 1). With k ordered categories, there are $k - 1$ binary sub-endpoints, together comprising the Lancaster decomposition [12].

In Table 1, the overall response rate would not differentiate the two treatment groups, whereas the complete response rate would. If one knew this ahead of time, then one might select the overall response rate. But the data could also turn out as in Table 2.

Now the situation is reversed, and it is the overall response rate that distinguishes the two treatment groups (30/30 or 100% in the active group vs 20/30 or 67% in the control group), whereas the complete response rate does not (10/30 or 33% in the active group vs 10/30 or 33% in the control group). If either pattern is possible, then it might not be clear, prior to collecting the data, which of the two outcome measures, complete response or overall response, would be preferred. The Smirnov test (see **Kolmogorov-Smirnov Tests**) can help, as it allows one to avoid having to prespecify the particular sub-endpoint to analyze. That is, it allows for the simultaneous testing of both outcome measures in the cases presented above, or of all $k - 1$ outcome measures more generally, while still preserving the overall Type I error rate. This is achieved by letting the data dictate the outcome measure (i.e., selecting that outcome measure that maximizes the test statistic), and then comparing the resulting test statistic not to its own null sampling distribution, but rather to the null sampling distribution of the maximally chosen test statistic.

Adaptive tests are more general than the Smirnov test, as they allow for an optimally chosen set of scores for use with a linear rank test, with the scores essentially being selected by the data [7]. That is, the Smirnov test allows for a data-dependent choice of

Table 3 Hypothetical data set #3

	No response	Partial response	Complete response
Control	10	10	10
Active	5	10	15

the cut point for a subsequent application on of an analogue of Fisher's exact test (see **Exact Methods for Categorical Data**), whereas adaptive tests allow the data to determine the numerical scores to be assigned to the columns for a subsequent linear rank test. Only if those scores are zero to the left of a given column and one to the right of it will the linear rank test reduce to Fisher's exact test. For the fictitious data in Tables 1 and 2, for example, the Smirnov test would allow for the data-dependent selection of the analysis of either the overall response rate or the complete response rate, but the Smirnov test would not allow for an analysis that exploits reinforcing effects. To see why this can be a problem, consider Table 3.

Now both of the aforementioned measures can distinguish the two treatment groups, and in the same direction, as the complete response rates are 50% and 33%, whereas the overall response rates are 83% and 67%. The problem is that neither one of these measures by itself is as large as the effect seen in Table 1 or Table 2. Yet, overall, the effect in Table 3 is as large as that seen in the previous two tables, but only if the reinforcing effects of both measures are considered. After seeing the data, one might wish to use a linear rank test by which numerical scores are assigned to the three columns and then the mean scores across treatment groups are compared. One might wish to use equally spaced scores, such as 1, 2, and 3, for the three columns. Adaptive tests would allow for this choice of scores to be used for Table 3 while preserving the Type I error rate by making the appropriate adjustment for the inherent multiplicity.

The basic idea behind adaptive tests is to subject the data to every conceivable set of scores for use with a linear rank test, and then compute the minimum of all the resulting P values. This minimum P value is artificially small because the data were allowed to select the test statistic (that is, the scores for use with the linear rank test). However, this minimum P value can be used not as a (valid) P value, but rather as a test statistic to be compared to the null sampling distribution of the minimal P value so

Table 2 Hypothetical data set #2

	No response	Partial response	Complete response
Control	10	10	10
Active	0	20	10

computed. As a result, the sample space can be partitioned into regions on which a common test statistic is used, and it is in this sense that the adaptive test allows the data to determine the test statistic, in a post hoc fashion. Yet, because of the manner in which the reference distribution is computed (on the basis of the exact design-based permutation null distribution of the test statistic [8] factoring in how it was selected on the basis of the data), the resulting test is exact. This adaptive testing approach was first proposed by Berger [2], but later generalized by Berger and Ivanova [7] to accommodate preferred alternative hypotheses and to allow for greater or lesser belief in these preferred alternatives.

Post hoc comparisons can and should be explored, but with some caveats. First, the criteria for selecting such comparisons to be made should be specified prospectively [1], when this is possible. Of course, it may not always be possible. Second, plausibility and subject area knowledge should be considered (as opposed to being based exclusively on statistical considerations) [1]. Third, if at all possible, these comparisons should be considered as hypothesis-generating, and should lead to additional studies to produce new data to test these hypotheses, which would have been post hoc for the initial experiments, but are now prespecified for the additional ones.

ACE Model

Introduction

The ACE model refers to a genetic epidemiological model that postulates that additive genetic factors (A) (*see Additive Genetic Variance*), common environmental factors (C), and specific environmental factors (E) account for individual differences in a phenotype (P) (*see Genotype*) of interest. This model is used to quantify the contributions of genetic and environmental influences to variation and is one of the fundamental models of basic genetic epidemiology [6]. Its name is therefore a simple acronym that allows researchers to communicate the fundamentals of a genetic model quickly, which makes it a useful piece of jargon for the genetic epidemiologist. The focus is thus the causes of variation between individuals. In mathematical terms, the total variance of a trait (V_P) is predicted to be the sum of the variance components: $V_P = V_A + V_C + V_E$, where V_A is the **additive genetic variance**, V_C the shared environmental variance (*see Shared Environment*), and V_E the specific environmental variance. The aim of fitting the ACE model is to answer questions about the importance of nature and nurture on individual differences such as ‘How much of the variation in a trait is accounted for by genetic factors?’ and ‘Do shared environmental factors contribute significantly to the trait variation?’. The first of these questions addresses **heritability**, defined as the proportion of the total variance explained by genetic factors ($h^2 = V_A / V_P$). The nature-nurture question is quite old. It was Sir **Francis Galton** [5] who first recognized that comparing the similarity of identical and fraternal twins yields information about the relative importance of heredity versus environment on individual differences. At the time, these observations seemed to conflict with Gregor Mendel’s classical experiments that demonstrated that the inheritance of model traits in carefully bred material agreed with a simple theory of particulate inheritance. **Ronald Fisher** [4] synthesized the views of Galton and Mendel by providing the first coherent account of how the ‘correlations between relatives’ could be explained ‘on the supposition of Mendelian inheritance’. In this chapter, we will first explain each of the sources of variation in quantitative traits in more detail. Second, we briefly discuss the utility of

the classical **twin design** and the tool of **path analysis** to represent the twin model. Finally, we introduce the concepts of model fitting and apply them by fitting models to actual data. We end by discussing the limitations and assumptions, as well as extensions of the ACE model.

Quantitative Genetics

Fisher assumed that the variation observed for a trait was caused by a large number of individual genes, each of which was inherited in a strict conformity to Mendel’s laws, the so-called polygenic model. If the model includes many environmental factors also of small and equal effect, it is known as the multifactorial model. When the effects of many small factors are combined, the distribution of trait values approximates the normal (Gaussian) distribution, according to the **central limit theorem**. Such a distribution is often observed for quantitative traits that are measured on a continuous scale and show individual variation around a mean trait value, but may also be assumed for qualitative or categorical traits, which represent an imprecise measurement of an underlying continuum of liability to a trait (*see Liability Threshold Models*), with superimposed thresholds [3]. The factors contributing to this variation can thus be broken down in two broad categories, genetic and environmental factors. Genetic factors refer to effects of loci on the genome that contain variants (or alleles). Using quantitative genetic theory, we can distinguish between additive and nonadditive genetic factors. Additive genetic factors (A) are the sum of all the effects of individual loci. Nonadditive genetic factors are the result of interactions between alleles on the same locus (dominance, D) or between alleles on different loci (**epistasis**). Environmental factors are those contributions that are nongenetic in origin and can be divided into shared and nonshared environmental factors. Shared environmental factors (C) are aspects of the environment that are shared by members of the same family or people who live together, and contribute to similarity between relatives. These are also called *common or between-family environmental factors*. Nonshared environmental factors (E), also called *specific, unique, or within-family environmental factors*, are factors unique to an individual. These E factors contribute to variation within family members, but not to their covariation. Various study designs exist to quantify the contributions

of these four sources of variation. Typically, these designs include individuals with different degrees of genetic relatedness and environmental similarity. One such design is the family study (*see Family History Versus Family Study Methods in Genetics*), which studies the correlations between parents and offspring, and/or siblings (in a nuclear family). While this design is very useful to test for familial resemblance, it does not allow us to separate additive genetic from shared environmental factors. The most popular design that does allow the separation of genetic and environmental (shared and unshared) factors is the classical twin study.

The Classical Twin Study

The classical twin study consists of a design in which data are collected from identical or monozygotic (MZ) and fraternal or dizygotic (DZ) twins reared together in the same home. MZ twins have identical genotypes, and thus share all their genes. DZ twins, on the other hand, share on average half their genes, as do regular siblings. Comparing the degree of similarity in a trait (or their correlation) provides an indication of the importance of genetic factors to the trait variability. Greater similarity for MZ versus DZ twins suggests that genes account for at least part of the trait. The recognition of this fact led to the development of heritability indices, based on the MZ and DZ correlations. Although these indices may provide a quick indication of the heritability, they may result in nonsensical estimates. Furthermore, in addition to genes, environmental factors that are shared by family members (or twins in this case) also contribute to familial similarity. Thus,

if environmental factors contribute to a trait and they are shared by twins, they will increase correlations equally between MZ and DZ twins. The relative magnitude of the MZ and DZ correlations thus tells us about the contribution of additive genetic (a^2) and shared environmental (c^2) factors. Given that MZ twins share their genotype and shared environmental factors (if reared together), the degree to which they differ informs us of the importance of specific environmental (e^2) factors.

If the twin similarity is expressed as correlations, one minus the MZ correlation is the proportion due to specific environment (Figure 1). Using the raw scale of measurement, this proportion can be estimated from the difference between the MZ covariance and the variance of the trait. With the trait variance and the MZ and DZ covariance as unique observed statistics, we can estimate the contributions of additive genes (A), shared (C), and specific (E) environmental factors, according to the genetic model. A useful tool to generate the expectations for the variances and covariances under a model is path analysis [11].

Path Analysis

A path diagram is a graphical representation of the model, and is mathematically complete. Such a path diagram for a genetic model, by convention, consists of boxes for the observed variables (the traits under study) and circles for the **latent variables** (the genetic and environmental factors that are not measured but inferred from data on relatives, and are standardized). The contribution of the latent variables to the variances of the observed variables is specified in the path

Figure 1 Derivation of variance components from twin correlations

coefficients, which are regression coefficients (represented by single-headed arrows from the latent to the observed variables). We further add two kinds of double-headed arrows to the path coefficients model. First, each of the latent variables has a double-headed arrow pointing to itself, which is fixed to 1.0. Note that we can either estimate the contribution of the latent variables through the path coefficients and standardize the latent variables or we can estimate the variances of the latent variables directly while fixing the paths to the observed variables. We prefer the path coefficients approach to the variance components model, as it generalizes much more easily to advanced models. Second, on the basis of quantitative genetic theory, we model the covariance between twins by adding double-headed arrows between the additive genetic and shared environmental latent variables. The correlation between the additive genetic latent variables is fixed to 1.0 for MZ twins, because they share all their genes. The corresponding value for DZ twins is 0.5, derived from biometrical principles [7]. The correlation between shared environmental latent variables is fixed to 1.0 for MZ and DZ twins, reflecting the equal environments assumption. Specific environmental factors do not contribute to covariance between twins, which is implied by omitting a double-headed arrow. The full path diagrams for MZ and DZ twins are presented in Figure 2.

The expected covariance between two variables in a path diagram may be derived by tracing all connecting routes (or ‘chains’) between the variables while following the rules of path analysis, which are: (a) trace backward along an arrow, change direction in a double-headed arrow and then trace forward, or simply forward from one variable to the other; this implies to trace through at most one two-way arrow in each chain of paths; (b) pass through each variable only once in each chain of paths. The expected covariance between two variables, or the expected variance of a variable, is computed by multiplying

together all the coefficients in a chain, and then summing over all legitimate chains. Using these rules, the expected covariance between the phenotypes of twin 1 and twin 2 for MZ twins and DZ twins can be shown to be:

$$\text{MZ cov} = \begin{bmatrix} a^2 + c^2 + e^2 & a^2 + c^2 \\ a^2 + c^2 & a^2 + c^2 + e^2 \end{bmatrix}$$

$$\text{DZ cov} = \begin{bmatrix} a^2 + c^2 + e^2 & 0.5a^2 + c^2 \\ 0.5a^2 + c^2 & a^2 + c^2 + e^2 \end{bmatrix}$$

This translation of the ideas of the theory into mathematical form comprises the stage of model building. Then, it is necessary to choose the appropriate study design, in this case the classical twin study, to generate critical data to test the model.

Model Fitting

The stage of model fitting allows us to compare the predictions with actual observations in order to evaluate how well the model fits the data using goodness-of-fit statistics. Depending on whether the model fits the data or not, it is accepted or rejected, in which case an alternative model may be chosen. In addition to the goodness-of-fit of the model, estimates for the genetic and environmental parameters are obtained. If a model fits the data, we can further test the significance of these parameters of the model by adding or dropping parameters and evaluate the improvement or decrease in model fit using likelihood-ratio tests. This is equivalent to estimating **confidence intervals**. For example, if the ACE model fits the data, we may drop the additive genetic (a) parameter and refit the model (now a CE model). The difference in the goodness-of-fit statistics for the two models, the ACE and the CE models, provides a likelihood-ratio test with one degree of freedom for the significance of a . If this test is significant, additive genetic factors contribute significantly to the variation

Figure 2 Path diagram for the ACE model applied to data from MZ and DZ twins

in the trait. If it is not, a could be dropped from the model, according to the principle of parsimony. Alternatively, we could calculate the confidence intervals around the parameters. If these include zero for a particular parameter, it indicates that the parameter is not significantly different from zero and could be dropped from the model. Given that significance of parameters is related to power of the study, confidence intervals provide useful information around the precision with which the point estimates are known. The main advantages of the model fitting approach are thus (a) assessing the overall model fit, (b) incorporating sample size and precision, and (c) providing sensible heritability estimates. Other advantages include that it (d) generalizes to the multivariate case and to extended pedigrees, (e) allows the addition of covariates, (f) makes use of all the available data, and (g) is suitable for selected samples. If we are interested in testing the ACE model and quantifying the degree to which genetic and environmental factors contribute to the variability of a trait, data need to be collected on relatively large samples of genetically informative relatives, for example, MZ and DZ twins. The ACE model can then be fitted either directly to the raw data or to summary statistics (covariance matrices) and decisions made about the model on the basis of the goodness-of-fit. There are several statistical modeling packages available capable of fitting the model, for example, EQS, SAS, Lisrel, and Mx (*see Structural Equation Modeling: Software*). The last program was designed specifically with genetic epidemiologic models in mind, and provides great flexibility in specifying both basic and advanced models [10]. Mx models are specified in terms of matrices, and matrix algebra is used to generate the expected covariance matrices or other statistics of the model to be fitted.

Example

We illustrate the ACE model, with data collected in the Virginia Twin Study of Adolescent Behavior

Development (VTSABD) [2]. One focus of the study is conduct disorder, which is characterized by a set of disruptive and destructive behaviors. Here we use a summed symptom score, normalized and standardized within age and sex, and limit the example to the data on 8–16-year old boys, rated by their mothers. Using the sum score data on 295 MZ and 176 DZ pairs of twins, we first estimated the means, variances, and covariances by maximum likelihood in Mx [10], separately for the two twins and the two zygosity groups (MZ and DZ, see Table 1). This model provides the overall likelihood of the data and serves as the ‘saturated’ model against which other models may be compared. It has 10 estimated parameters and yields a -2 times log-likelihood of 2418.575 for 930 degrees of freedom, calculated as the number of observed statistics (940 nonmissing data points) minus the number of estimated parameters. First, we tested the equality of means and variances by twin order and zygosity by imposing equality constraints on the respective parameters. Neither means nor variances were significantly different for the two members of a twin pair, nor did they differ across zygosity ($\chi^2_6 = 5.368$, $p = .498$).

Then we fitted the ACE model, thus partitioning the variance into additive genetic, shared, and specific environmental factors. We estimated the means freely as our primary interest is in the causes of individual differences. The likelihood ratio test – obtained by subtracting the -2 log-likelihood of the saturated model from that of the ACE model (2421.478) for the difference in degrees of freedom of the two models (933–930) – indicates that the ACE model gives an adequate fit to the data ($\chi^2_3 = 2.903$, $p = .407$). We can evaluate the significance of each of the parameters by estimating confidence intervals, or by fitting submodels in which we fix one or more parameters to zero. The series of models typically tested includes the ACE, AE, CE, E, and ADE models. Alternative models can be compared by several fit indices,

Table 1 Means and variances estimated from the raw data on conduct disorder in VTSABD twins

	Monozygotic male twins (MZM)		Dizygotic male twins (DZM)	
	T1	T2	T1	T2
Expected means	–0.0173	–0.0228	0.0590	–0.0688
Expected covariance matrix	T1	0.9342	T1	1.0908
	T2	0.5930	T2	0.3898
		0.8877		0.9030

Table 2 Goodness-of-fit statistics and parameter estimates for conduct disorder in VTSABD twins

Model	χ^2	df	p	AIC	$\Delta\chi^2$	df	a^2	c^2	e^2
ACE	2.903	3	.407	-3.097			.57 (.33 – .72)	.09 (.00 – .31)	.34 (.28 – .40)
AE	3.455	4	.485	-4.545	0.552	1	.66 (.60 – .72)		.34 (.28 – .40)
CE	26.377	4	.000	18.377	23.475	1		.55 (.48 – .61)	.45 (.39 – .52)
E	194.534	5	.000	184.534	191.63	2			1.00
ADE	3.455	3	.327	-2.545			.66 (.30 – .72)	d^2 .00 (.00 – .36)	.34 (.28 – .40)

AIC: Akaike's information criterion; a^2 : additive genetic variance component; c^2 : shared environmental variance component; e^2 : specific environmental variance component.

for example, the **Akaike's Information Criterion** (AIC; [1]), which takes into account both goodness-of-fit and parsimony and favors the model with the lowest value for AIC. Results from fitting these models are presented in Table 2. Dropping the shared environmental parameter c did not deteriorate the fit of the model. However, dropping the a path resulted in a significant decrease in model fit, suggesting that additive genetic factors account for part of the variation observed in conduct disorder symptoms, in addition to specific environmental factors. The latter are always included in the models for two main reasons. First, almost all variables are subject to error. Second, the likelihood is generally not defined when twins are predicted to correlate perfectly. The same conclusions would be obtained from judging the confidence intervals around the parameters a^2 (which do not include zero) and c^2 (which do include zero). Not surprisingly, the E model fits very badly, indicating highly significant family resemblance.

Typically, the ADE model (with dominance instead of common environmental influences) is also fitted, predicting a DZ correlation less than half the MZ correlation. This is the opposite expectation of the ACE model that predicts a DZ correlation greater than half the MZ correlation. Given that dominance (d) and shared environment (c) are confounded in the classical twin design and that the ACE and ADE models are not nested, both are fitted and preference is given to the one with the best absolute goodness-of-fit, in this case the ACE model. Alternative designs, for example, twins reared apart, provide additional unique information to identify and simultaneously estimate c and d separately. In this example, we conclude that the AE model is the best fitting and most parsimonious model to explain variability in conduct disorder symptoms in adolescent boys rated by their mothers in the VTSABD. Additive genetic factors account for

two-thirds of the variation, with the remaining one-third explained by specific environmental factors. A more detailed description of these methods may be found in [8].

Limitations and Assumptions

Although the classical twin study is a powerful design to infer the causes of variation in a trait of interest, it is important to reflect on the limitations when interpreting results from fitting the ACE model to twin data. The power of the study depends on a number of factors, including among others the study design, the sample size, the effect sizes of the components of variance, and the significance level [9]. Further, several assumptions are made when fitting the ACE model. First, it is assumed that the effects of A, C, and E are linear and additive (i.e., no genotype by environment interaction) and mutually independent (i.e., no genotype-environment covariance). Second, the effects are assumed to be equal across twin order and zygosity. Third, we assume that the contribution of environmental factors to twins' similarity for a trait is equal for MZ and DZ twins (equal environments assumption). Fourth, no direct influence exists from a twin on his/her co-twin (no reciprocal sibling environmental effect). Finally, the parental phenotypes are assumed to be independent (random mating). Some of these assumptions may be tested by extending the twin design.

Extensions

Although it is important to answer the basic questions about the importance of genetic and environmental factors to variation in a trait, the information obtained remains descriptive. However, it forms the basis for

more advanced questions that may inform us about the nature and kind of the genetic and environmental factors. Some examples of these questions include: Is the contribution of genetic and/or environmental factors the same in males and females? Is the heritability equal in children, adolescents, and adults? Do the same genes account for variation in more than one phenotype, or thus explain some or all of the covariation between the phenotypes? Does the impact of genes and environment change over time? How much parent-child similarity is due to shared genes versus shared environmental factors?

This basic model can be extended in a variety of ways to account for sex limitation, genotype $\times$ environment interaction, sibling interaction, and to deal with multiple variables measured simultaneously (multivariate genetic analysis) or longitudinally (developmental genetic analysis). Other relatives can also be included, such as siblings, parents, spouses, and children of twins, which may allow better separation of genetic and cultural transmission and estimation of assortative mating and twin and sibling environment. The addition of measured genes (genotypic data) or measured environments may further refine the partitioning of the variation, if these measured variables are linked or associated with the phenotype of interest. The ACE model is thus the cornerstone of modeling the causes of variation.

Adaptive Random Assignment

Adaptive Allocation

The primary objective of a comparative trial is to provide a precise and valid treatment comparison (*see Clinical Trials and Intervention Studies*). Another objective may be to minimize exposure to the inferior treatment, the identity of which may be revealed during the course of the study. The two objectives together are often referred to as *bandit problems* [5], an essential feature of which is to balance the conflict between information gathering (benefit to society) and the immediate payoff that results from using what is thought to be best at the time (benefit to the individual). Because **randomization** promotes (but does not guarantee [3]) comparability among the study groups in both known and unknown covariates, randomization is rightfully accepted as the ‘gold standard’ solution for the first objective, valid comparisons. There are four major classes of randomization procedures, including unrestricted randomization, restricted randomization, covariate-adaptive randomization, and response-adaptive randomization [6]. As the names would suggest, the last two classes are adaptive designs.

Unrestricted randomization is not generally used in practice because it is susceptible to chronological bias, and this would interfere with the first objective, the valid treatment comparison. Specifically, the lack of restrictions allows for long runs of one treatment or another, and hence the possibility that at some point during the study, even at the end, the treatment group sizes could differ substantially. If this is the case, so that more ‘early’ subjects are in one treatment group and more ‘late’ subjects are in another, then any apparent treatment effects would be confounded with time effects. Restrictions on the randomization are required to ensure that at no point during the study are the treatment group sizes too different. Yet, too many restrictions lead to a predictable allocation sequence, which can also compromise validity. It can be a challenge to find the right balance of restrictions on the randomization [4], and sometimes a adaptive design is used. Perhaps the most common covariate-adaptive design is minimization [7], which minimizes a covariate imbalance function.

Covariate-adaptive Randomization Procedures

Covariate-adaptive (also referred to as *baseline-adaptive*) randomization is similar in intention to **stratification**, but takes the further step of balancing baseline covariate distributions dynamically, on the basis of the existing baseline composition of the treatment groups at the time of allocation. This procedure is usually used when there are too many important prognostic factors for stratification to handle reasonably (there is a limit to the number of strata that can be used [8]). For example, consider a study of a behavioral intervention with only 50 subjects, and 6 strong predictors. Even if each of these 6 predictors is binary, that still leads to 64 strata, and on average less than one subject per stratum. This situation would defeat the purpose of stratification, in that most strata would then not have both treatment groups represented, and hence no matching would occur. The treatment comparisons could then not be considered within the strata.

Unlike stratified randomization, in which an allocation schedule is generated separately for each stratum prior to the start of study, covariate-adaptive procedures are dynamic. The treatment assignment of a subject is dependent on the subject’s vector of covariates, which will not be determined until his or her arrival. Minimization [7] is the most commonly used covariate-adaptive procedure. It ensures excellent balance between the intervention groups for specified prognostic factors by assigning the next participant to whichever group minimizes the imbalance between groups on specified prognostic factors. The balance can be with respect to main effects only, say gender and smoking status, or it can mimic stratification and balance with respect to joint distributions, as in the cross classification of smoking status and gender. In the former case, each treatment group would be fairly equally well represented among smokers, nonsmokers, males, and females, but not necessarily among female smokers, for example.

As a simple example, suppose that the trial is underway, and 32 subjects have already been enrolled, 16 to each group. Suppose further that currently Treatment Group A has four male smokers, five female smokers, four male nonsmokers, and three female nonsmokers, while Treatment Group B has five male smokers, six female smokers, two male nonsmokers, and three female nonsmokers. The 33rd subject to be enrolled is a male smoker. Provisionally

2 Adaptive Random Assignment

place this subject in Treatment Group A, and compute the marginal male imbalance to be $(4 + 4 + 1 - 5 - 2) = 2$, the marginal smoker imbalance to be $(4 + 5 + 1 - 5 - 6) = -1$, and the joint male smoker imbalance to be $(4 + 1 - 5) = 0$. Now provisionally place this subject in Treatment Group B and compute the marginal male imbalance to be $(4 + 4 - 5 - 2 - 1) = 0$, the marginal smoker imbalance to be $(4 + 5 - 5 - 6 - 1) = -2$, and the joint male smoker imbalance to be $(4 - 5 - 1) = -2$. Using the joint balancing, Treatment Group A would be preferred. The actual allocation may be deterministic, as in simply assigning the subject to the group that leads to better balance, A in this case, or it may be stochastic, as in making this assignment with high probability. For example, one might add one to the absolute value of each imbalance, and then use the ratios as probabilities.

So here the probability of assignment to A would be $(2 + 1)/[(0 + 1) + (2 + 1)] = 3/4$ and the probability of assignment to B would be $(0 + 1)/[(2 + 1) + (0 + 1)] = 1/4$. If we were using the marginal balancing technique, then a weight function could be used to weigh either gender or smoking status more heavily than the other or they could each have the same weight. Either way, the decision would again be based, either deterministically or stochastically, on which treatment group minimizes the imbalance, and possibly by how much.

Response-adaptive Randomization Procedures

In response-adaptive randomization, the treatment allocations depend on the previous subject outcomes, so that the subjects are more likely to be assigned to the ‘superior’ treatment, or at least to the one that is found to be superior so far. This is a good way to address the objective of minimizing exposure to an inferior treatment, and possibly the only way to address both objectives discussed above [5]. Response-adaptive randomization procedures may determine the allocation ratios so as to optimize certain criteria, including minimizing the expected number of treatment failures, minimizing the expected number of patients assigned to the inferior treatment, minimizing the total sample size, or minimizing the total cost. They may also follow intuition, often as urn models. A typical urn model starts with k balls of each color, with each color representing a distinct treatment group (that is, there is a

one-to-one correspondence between the colors of the balls in the urn and the treatment groups to which a subject could be assigned). A ball is drawn at random from the urn to determine the treatment assignment. Then the ball is replaced, possibly along with other balls of the same color or another color, depending on the response of the subject to the initial treatment [10].

With this design, the allocation probabilities depend not only on the previous treatment assignments but also on the responses to those treatment assignments; this is the basis for calling such designs ‘response adaptive’, so as to distinguish them from covariate-adaptive designs. Perhaps the most well-known actual trial that used a response-adaptive randomization procedure was the Extra Corporeal Membrane Oxygenation (ECMO) Trial [1]. ECMO is a surgical procedure that had been used for infants with respiratory failure who were dying and were unresponsive to conventional treatment of ventilation and drug. Data existed to suggest that the ECMO treatment was safe and effective, but no randomized controlled trials had confirmed this. Owing to prior data and beliefs, the ECMO investigators were reluctant to use equal allocation. In this case, response-adaptive randomization is a practical procedure, and so it was used.

The investigators chose the randomized play-the-winner RPW(1,1) rule for the trial. This means that after a ball is chosen from the urn and replaced, one additional ball is added to the urn. This additional ball is of the same color as the previously chosen ball if the outcome is a response (survival, in this case). Otherwise, it is of the opposite color. As it turns out, the first patient was randomized to the ECMO treatment and survived, so now ECMO had two balls to only one conventional ball. The second patient was randomized to conventional therapy, and he died. The urn composition then had three ECMO balls and one control ball. The remaining 10 patients were all randomized to ECMO, and all survived. The trial then stopped with 12 total patients, in accordance with a prespecified stopping rule.

At this point, there was quite a bit of controversy regarding the validity of the trial, and whether it was truly a controlled trial (since only one patient received conventional therapy). Comparisons between the two treatments were questioned because they were based on a sample of size 12, again, with only one subject in one of the treatment groups. In fact, depending

on how the data were analyzed, the P value could range from 0.001 (an analysis that assumes complete randomization and ignores the response-adaptive randomization; [9]) to 0.620 (a permutation test that conditions on the observed sequences of responses; [2]) (see **Permutation Based Inference**).

Two important lessons can be learned from the ECMO Trial. First, it is important to start with more than one ball corresponding to each treatment in the urn. It can be shown that starting out with only one ball of each treatment in the urn leads to instability with the randomized play-the-winner rule. Second, a minimum sample size should be specified to avoid the small sample size found in ECMO. It is also possible to build in this requirement by starting the trial as a nonadaptively randomized trial, until a minimum number of patients are recruited to each treatment group. The results of an interim analysis at this point can determine the initial constitution of the urn, which can be used for subsequent allocations, and updated accordingly. The allocation probability will then eventually favor the treatment with fewer failures or more success, and the proportion of allocations to the better arm will converge to one.

Adaptive Sampling

Traditional sampling methods do not allow the selection for a sampling unit to depend on the previous observations made during an initial survey; that is, sampling decisions are made and fixed prior to the survey. In contrast, adaptive sampling refers to a sampling technique in which the procedure for selecting sites or units to be included in the sample may depend on the values of the variable of interest already observed during the study [10]. Compared to the traditional fixed sampling procedure, adaptive sampling techniques often lead to more effective results.

To motivate the development of adaptive sampling procedures, consider, for example, a population clustered over a large area that is generally sparse or empty between clusters. If a simple random sample (see **Simple Random Sampling**) is used to select geographical subsections of the large area, then many of the units selected may be empty, and many clusters will be missed. It would, of course, be possible to oversample the clusters if it were known where they are located. If this is not the case, however, then adaptive sampling might be a reasonable procedure. An initial sample of locations would be considered. Once individuals are detected in one of the selected units, the neighbors of that unit might also be added to the sample. This process would be iterated until a cluster sample is built.

This adaptive approach would seem preferable in environmental pollution surveys, drug use epidemiology studies, market surveys, studies of rare animal species, and studies of contagious diseases [12]. In fact, an adaptive approach was used in some important surveys. For example, moose surveys were conducted in interior Alaska by using an adaptive sampling design [3]. Because the locations of highest moose abundance was not known prior to the survey, the spatial location of the next day's survey was based on the current results [3]. Likewise, Roesch [4] estimated the prevalence of insect infestation in some hardwood tree species in Northeastern North America. The species of interest were apt to be rare and highly clustered in their distribution, and therefore it was difficult to use traditional sampling procedures. Instead, an adaptive sampling was used. Once a tree of the species was found, an area of specified radius around it would be searched for additional individuals of the species [4].

Adaptive sampling offers the following advantages [10, 12]:

1. Adaptive sampling takes advantage of population characteristics to obtain more precise estimates of population abundance or density. For example, populations of plants, animals, minerals, and fossil fuels tend to exhibit aggregation patterns because of schooling, flocking, and environmental patchiness. Because the location and shape of the aggregation cannot be predicted before a survey, adaptive sampling can provide a dynamic way to increase the effectiveness of the sampling effort.
2. Adaptive sampling reduces unit costs and time, and improves the precision of the results for a given sample size. Adaptive sampling increases the number of observations, so that more endangered species are observed, and more individuals are monitored. This can result in good estimators of interesting parameters. For example, in spatial sampling, adaptive cluster sampling can provide unbiased efficient estimators of the abundance of rare, clustered populations.
3. Some theoretical results show that adaptive procedures are optimal in the sense of giving the most precise estimates with a given amount of sampling effort.

There are also problems related to adaptive sampling [5]:

1. The final sample size is random and unknown, so the appropriate theories need to be developed for a sampling survey with a given precision of estimation.
2. An inappropriate criterion for adding neighborhoods will affect sample units and compromise the effectiveness of the sampling effort.
3. Great effort must be expended in locating initial units.

Although the idea of adaptive sampling was proposed for some time, some of the practical methods have been developed only recently. For example, adaptive cluster sampling was introduced by Thompson in 1990 [6]. Other new developments include two-stage adaptive cluster sampling [5], adaptive cluster double sampling [2], and inverse adaptive cluster sampling [1]. The basic idea behind adaptive cluster sampling is illustrated in

Figure 1 Adaptive cluster sampling and its result (From Thompson, S.K. (1990). Adaptive cluster sampling, *Journal of the American Statistical Association* **85**, 1050–1059 [6])

Figure 1 [6]. There are 400 square units. The following steps are carried out in the sampling procedure.

1. An initial random sample of 10 units is shown in Figure 1(a).
2. In adaptive sampling, we need to define a neighborhood for a sampling unit. A neighborhood can be decided by a prespecified and nonadaptive rule. In this case, the neighborhood of a unit is its set of adjacent units (left, right, top, and bottom).
3. We need to specify a criterion for searching a neighbor. In this case, once one or more objects are observed in a selected unit, its neighborhood is added to the sample.
4. Repeat step 3 for each neighbor unit until no object is observed. In this case, the sample consists of 45 units. See Figure 1(b).

Stratified adaptive cluster sampling (*see Stratification*) is an extension of the adaptive cluster approach. On the basis of prior information about the population or simple proximity of the units, units that are thought to be similar to each other are grouped into strata. Following an initial stratified sample, additional units are added to the sample from the neighborhood of any selected unit when it satisfies the criterion. If additional units are added to the sample, where the high positive identifications are observed, then the sample mean will overestimate the population mean. Unbiased estimators can be obtained by making use of new observations in addition to the observations initially selected.

Thompson [8] proposed several types of estimators that are unbiased for the population mean or total. Some examples are estimators based on expected numbers of initial intersections, estimators based on initial intersection probabilities, and modified estimators based on the Rao–Blackwell method.

Another type of adaptive sampling is the design with primary and secondary units. Systematic adaptive cluster sampling and strip adaptive cluster sampling belong to this type. For both sampling schemes, the initial design could be systematic sampling or strip sampling. That is, the initial design is selected in terms of primary units, while subsequent sampling is in terms of secondary units. Conventional estimators of the population mean or total are biased with such a procedure, so Thompson [7] developed unbiased estimators, such as estimators based on partial selection probabilities and estimators based on partial inclusion probabilities. Thompson [7] has shown that by using a point pattern representing locations of individuals or objects in a spatially aggregated population, the adaptive design can be substantially more efficient than its conventional counterparts.

Commonly, the criterion for additional sampling is a fixed and prespecified rule. In some surveys, however, it is difficult to decide on the fixed criterion ahead of time. In such cases, the criterion could be based on the observed sample values. Adaptive cluster sampling based on order statistics is particularly appropriate for some situations, in which the investigator wishes to search for high values of the variable of interest in addition to estimating the overall mean

or total. For example, the investigator may want to find the pollution ‘hot spots’. Adaptive cluster sampling based on order statistics is apt to increase the probability of observing units with high values, while at the same time allowing for unbiased estimation of the population mean or total. Thompson has shown that these estimators can be improved by using the Rao–Blackwell method [9].

Thompson and Seber [11] proposed the idea of detectability in adaptive sampling. Imperfect detectability is a source of nonsampling error in the natural survey and human population survey. This is because even if a unit is included in the survey, it is possible that not all of the objects can be observed. Examples are a vessel survey of whales and a survey of homeless people. To estimate the population total in a survey with imperfect detectability, both the sampling design and the detection probabilities must be taken into account. If imperfect detectability is not taken into account, then it will lead to underestimates of the population total. In the most general case, the values of the variable of interest are divided by the detection probability for the observed object, and then estimation methods without detectability problems are used.

Finally, regardless of the design on which the sampling is obtained, optimal sampling strategies should be considered. Bias and mean-square errors are usually measured, which lead to reliable results.

Additive Constant Problem

Introduction

Consider a set of objects or stimuli, for example, a set of colors, and an experiment that produces information about the pairwise dissimilarities of the objects. From such information, two-way **multidimensional scaling** (MDS) constructs a graphical representation of the objects. Typically, the representation consists of a set of points in a low-dimensional Euclidean space. Each point corresponds to one object. Metric two-way MDS constructs the representation in such a way that the pairwise distances between the points approximate the pairwise dissimilarities of the objects.

In certain types of experiments, for example, **Fechner's** method of paired comparisons, Richardson's [7] method of triadic combinations, Klingberg's [4] method of multidimensional rank order, and Torgerson's [9] complete method of triads, the observed dissimilarities represent comparative distances, that is, distances from which an unknown scalar constant has been subtracted. The additive constant problem is the problem of estimating this constant.

The additive constant problem has been formulated in different ways, most notably by Torgerson [9], Messick and Abelson [6], Cooper [2], Saito [8], and Cailliez [1]. In assessing these formulations, it is essential to distinguish between the cases of errorless and fallible data. The former is the province of distance geometry, for example, determining whether or not adding any constant converts the set of dissimilarities to a set of Euclidean distances. The latter is the province of computational and graphical statistics, namely, finding an effective low-dimensional representation of the data.

Classical Formulation

The additive constant problem was of fundamental importance to Torgerson [9], who conceived MDS as comprising three steps: (1) obtain a scale of comparative distances between all pairs of objects; (2) convert the comparative distances to absolute

(Euclidean) distances by adding a constant; and (3) construct a configuration of points from the absolute distances. Here, the comparative distances are given and (1) need not be considered. Discussion of (2) is facilitated by first considering (3).

Suppose that we want to represent a set of objects in p -dimensional Euclidean space. First, we let δ_{ij} denote the dissimilarity of objects i and j . Notice that $\delta_{ii} = 0$, that is, an object is not dissimilar from itself, and that $\delta_{ij} = \delta_{ji}$. It is convenient to organize these dissimilarities into a matrix, Δ . Next, we let X denote a configuration of points. Again, it is convenient to think of X as a matrix in which row i stores the p coordinates of point i . Finally, let $d_{ij}(X)$ denote the Euclidean distances between points i and j in configuration X . As with the dissimilarities, it is convenient to organize the distances into a matrix, $D(X)$. Our immediate goal is to find a configuration whose interpoint distances approximate the specified dissimilarities, that is, to find an X for which $D(X) \approx \Delta$.

The embedding problem of classical distance geometry inquires if there is a configuration whose interpoint distances *equal* the specified dissimilarities. Torgerson [9] relied on the following solution. First, one forms the matrix of squared dissimilarities, $\Delta * \Delta = (\delta_{ij}^2)$. Next, one transforms the squared dissimilarities by double centering (from each δ_{ij}^2 , subtract the averages of the squared dissimilarities in row i and column j , then add the overall average of all squared dissimilarities), then multiplying by $-1/2$. In Torgerson's honor, this transformation is often denoted τ . The resulting matrix is $B^* = \tau(\Delta * \Delta)$. There exists an X for which $D(X) = \Delta$ if and only if all of the **eigenvalues** (latent roots) of B^* are nonnegative and at most p of them are strictly positive. If this condition is satisfied, then the number of strictly positive eigenvalues is called the *embedding dimension* of Δ . Furthermore, if $XX^t = B^*$, then $D(X) = \Delta$.

For Torgerson [9], Δ was a matrix of comparative distances. The dissimilarity matrix to be embedded was $\Delta(c)$, obtained by adding c to each δ_{ij} for which $i \neq j$. The scalar quantity c is the additive constant. In the case of errorless data, Torgerson proposed choosing c to minimize the embedding dimension of $\Delta(c)$. His procedure was criticized and modified by Messick and Abelson [6], who argued that Torgerson underestimated c . Alternatively, one can always choose c sufficiently large that $\Delta(c)$

2 Additive Constant Problem

can be embedded in $(n - 2)$ -dimensional Euclidean space, where n is the number of objects. Cailliez [1] derived a formula for the smallest c for which this embedding is possible.

In the case of fallible data, a different formulation is required. Torgerson argued:

‘This means that with fallible data the condition that B^* be positive semidefinite as a criterion for the points’ existence in real space is not to be taken too seriously. What we would like to obtain is a B^* -matrix whose latent roots consist of

1. A few large positive values (the “true” dimensions of the system), and
2. The remaining values small and distributed about zero (the “error” dimensions).

It may be that for fallible data we are asking the wrong question. Consider the question, “For what value of c will the points be most nearly (in a least-squares sense) in a space of a given dimensionality?”’

Torgerson’s [9] question was posed by de Leeuw and Heiser [3] as the problem of finding the symmetric positive semidefinite matrix of rank $\leq p$ that best approximates $\tau(\Delta(c) * \Delta(c))$ in a least-squares sense. This problem is equivalent to minimizing

$$\zeta(c) = \sum_{i=1}^p [\max(\lambda_i(c), 0) - \lambda_i(c)]^2 + \sum_{i=p+1}^n \lambda_i(c)^2, \quad (1)$$

where $\lambda_1(c) \geq \dots \geq \lambda_n(c)$ are the eigenvalues of $\tau(\Delta(c) * \Delta(c))$. The objective function ζ may have nonglobal minimizers. However, unless n is very large, modern computers can quickly graph $\zeta(\cdot)$, so that the basin containing the global minimizer can be identified by visual inspection. The global minimizer can then be found by a unidimensional search algorithm.

Other Formulations

In a widely cited article, Saito [8] proposed choosing c to maximize a ‘normalized index of fit,’

$$P(c) = \frac{\sum_{i=1}^p \lambda_i^2(c)}{\sum_{i=1}^n \lambda_i^2(c)}. \quad (2)$$

Saito assumed that $\lambda_p(c) > 0$, which implies that $[\max(\lambda_i(c), 0) - \lambda_i(c)]^2 = 0$ for $i = 1, \dots, p$. One can then write

$$P(c) = 1 - \frac{\sum_{i=p+1}^n \lambda_i^2(c)}{\sum_{i=1}^n \lambda_i^2(c)} = 1 - \frac{\zeta(c)}{\eta(c)}. \quad (3)$$

Hence, Saito’s formulation is equivalent to minimizing $\zeta(c)/\eta(c)$, and it is evident that his formulation encourages choices of c for which $\eta(c)$ is large. Why one should prefer such choices is not so clear. Trosset, Baggerly, and Pearl [10] concluded that Saito’s criterion typically results in a larger additive constant than would be obtained using the classical formulation of Torgerson [9] and de Leeuw and Heiser [3].

A comprehensive formulation of the additive constant problem is obtained by introducing a loss function, σ , that measures the discrepancy between a set of p -dimensional Euclidean distances and a set of dissimilarities. One then determines both the additive constant and the graphical representation of the data by finding a pair (c, D) that minimizes $\sigma(D, \Delta(c))$. The classical formulation’s loss function is the squared error that results from approximating $\tau(\Delta(c) * \Delta(c))$ with $\tau(D * D)$. This loss function is sometimes called the *strain criterion*. In contrast, Cooper’s [2] loss function was Kruskal’s [5] raw stress criterion, the squared error that results from approximating $\Delta(c)$ with D . Although the raw stress criterion is arguably more intuitive than the strain criterion, Cooper’s formulation cannot be reduced to a unidimensional optimization problem.

Additive Genetic Variance

The starting point for gene finding is the observation of population variation in a certain trait. This ‘observed’, or phenotypic, variation may be attributed to genetic and environmental causes. Although environmental causes of phenotypic variation should not be ignored and are highly interesting, in the following section we will focus on the biometric model underlying genetic causes of variation, specifically *additive* genetic causes of variation.

Within a population, one, two, or many different alleles may exist for a gene (*see Allelic Association*). Uniallelic systems will not contribute to population variation. For simplicity, we assume in this treatment one gene with two possible alleles, alleles A1 and A2. By convention, allele A1 has frequency p , while allele A2 has frequency q , and $p + q = 1$. With two alleles, there are three possible **genotypes**: A1A1, A1A2, and A2A2, with corresponding genotypic frequencies p^2 , $2pq$, and q^2 (assuming random mating, equal viability of alleles, no selection, no migration and no mutation, *see* [3]). The genotypic effect on a phenotypic trait (i.e., *the genotypic value*) of genotype A1A1, is by convention called ‘ a ’ and the effect of genotype A2A2 ‘ $-a$ ’. The effect of the heterozygous genotype A1A2 is called ‘ d ’. If the genotypic value of the heterozygote lies exactly at the midpoint of the genotypic values of the two homozygotes ($d = 0$), there is said to be no genetic dominance. If allele A1 is completely dominant over allele A2, effect d equals effect a . If d is larger than a , there is overdominance. If d is unequal to zero and the two alleles produce three discernable phenotypes of the trait, d is unequal to a . This model is also known as the *classical biometrical model* [3, 6] (*see* Figure 1 for a worked example).

The genotypic contribution of a gene to the population mean of a trait (i.e., the mean effect of a gene, or μ) is the sum of the products of the frequencies and the genotypic values of the different genotypes:

$$\begin{aligned} \text{Mean effect} &= (ap^2) + (2pqd) + (-aq^2) \\ &= a(p - q) + 2pqd. \end{aligned} \quad (1)$$

This mean effect of a gene consists of two components: the contribution of the homozygotes [$a(p - q)$] and the contribution of the heterozygotes

[$2pqd$]. If there is no dominance, that is d equals zero, there is no contribution of the heterozygotes and the mean is a simple function of the allele frequencies. If d equals a , which is defined as complete dominance, the population mean becomes a function of the square of the allele frequencies; substituting d for a gives $a(p - q) + 2pqa$, which simplifies to $a(1 - 2q^2)$.

Complex traits such as height or weight are not very likely influenced by a single gene, but are assumed to be influenced by many genes. Assuming only additive and independent effects of all of these genes, the expectation for the population mean (μ) is the sum of the mean effects of all the separate genes, and can formally be expressed as $\mu = \sum a(p - q) + 2 \sum dpq$ (*see* also Figure 2).

Average Effects and Breeding Values

Let us consider a relatively simple trait that seems to be mainly determined by genetics, for example eye color. As can be widely observed, when a brown-eyed parent mates with a blue-eyed parent, their offspring will not be either brown eyed or blue eyed, but may also have green eyes. At present, three genes are known to be involved in human eye color. Two of these genes lie on chromosome 15: the EYCL2 and EYCL3 genes (also known as the BEY1 and BEY2 gene respectively) and one gene lies on chromosome 19; the EYCL1 gene (or GEY gene) [1, 2]. For simplicity, we ignore one gene (BEY1), and assume that only GEY and BEY2 determine eye color. The BEY2 gene has two alleles: a blue allele and a brown allele. The brown allele is completely dominant over the blue allele. The GEY gene also has two alleles: a green allele and a blue allele. The green allele is dominant over the blue allele of GEY but also over the blue allele of BEY2. The brown allele of BEY2 is dominant over the green allele of GEY. Let us assume that the brown-eyed parent has genotype *brown–blue* for the BEY2 gene and *green–blue* for the GEY gene, and that the blue-eyed parent has genotype *blue–blue* for both the BEY2 gene and the GEY gene. Their children can be (a) brown eyed: *brown–blue* for the BEY2 gene and either *blue–blue* or *green–blue* for the GEY gene; (b) green eyed: *blue–blue* for the BEY2 gene and *green–blue* for the GEY gene; (c) blue eyed: *blue–blue* for the BEY2 gene and *blue–blue* for the GEY gene. The possibility of having green-eyed children from a brown-eyed

2 Additive Genetic Variance

Figure 1 Worked example of genotypic effects, average effects, breeding values, and genetic variation. Assume body height is determined by a single gene with two alleles A1 and A2, and frequencies $p = 0.6$, $q = 0.4$. Body height differs per genotype: A2A2 carriers are 167 cm tall, A1A2 carriers are 175 cm tall, and A1A1 carriers are 191 cm tall. Half the difference between the heights of the two homozygotes is a , which is 12 cm. The midpoint of the two homozygotes is 179 cm, which is also the intercept of body height within the population, that is, subtracting 179 from the three genotypic means scales the midpoint to zero. The deviation of the heterozygote from the midpoint (d) = -4 cm. The mean effect of this gene to the population mean is thus $12(0.6 - 0.4) + 2 * 0.6 * 0.4 * -4 = 0.48$ cm. To calculate the average effect of allele A1 (α_1) c, we sum the product of the conditional frequencies and genotypic values of the two possible genotypes, including the A1 allele. The two genotypes are A1A1 and A1A2, with genotypic values 12 and -4. Given one A1 allele, the frequency of A1A1 is 0.6 and of A1A2 is 0.4. Thus, $12 * 0.6 - 4 * 0.4 = 5.6$. We need to subtract the mean effect of this gene (0.48) from 5.6 to get the average effect of the A1 allele (α_1): $5.6 - 0.48 = 5.12$. Similarly, the average effect of the A2 allele (α_2) can be shown to equal -7.68. The breeding value of A1A1 carriers is the sum of the average effects of the two A1 alleles, which is $5.12 + 5.12 = 10.24$. Similarly, for A1A2 carriers this is $5.12 - 7.68 = 2.56$ and for A2A2 carriers this is $-7.68 - 7.68 = -15.36$. The genetic variance (V_G) related to this gene is 82.33, where V_A is 78.64 and V_D is 3.69

Figure 2 The combined discrete effects of many single genes result in continuous variation in the population. ^aBased on 8087 adult subjects from the Dutch Twin Registry (<http://www.tweelingenregister.org>)

parent and a blue-eyed parent is of course a consequence of the fact that parents transmit alleles to their offspring and not their genotypes. Therefore, parents cannot directly transmit their genotypic values a , d , and $-a$ to their offspring. To quantify the transmission of genetic effects from parents to offspring, and ultimately to decompose the observed variance in the offspring generation into genetic and environmental components, the concepts *average effect* and *breeding value* have been introduced [3].

Average effects are a function of genotypic values and allele frequencies within a population. The average effect of an allele is defined as ‘.. the mean deviation from the population mean of individuals which received that allele from one parent, the allele received from the other parent having come at random from the population’ [3]. To calculate the average effects denoted by α_1 and α_2 of alleles A1 and A2 respectively, we need to determine the frequency of the A1 (or A2) alleles in the genotypes of the offspring coming from a single parent. Again, we assume a single locus system with two alleles. If there is random mating between gametes carrying the A1 allele and gametes from the population, the frequency with which the A1 gamete unites with another gamete containing A1 (producing an A1A1 genotype in the offspring) equals p , and the frequency with which the gamete containing the A1 gamete unites with a gamete carrying A2 (producing an A1A2 genotype in the offspring) is q . The genotypic value of the genotype A1A1 in the offspring is a and the genotypic value of A1A2 in the offspring is d , as defined earlier. The mean value of the genotypes that can be produced by a gamete carrying the A1 allele equals the sum of the products of the frequency and the genotypic value. Or, in other terms, it is $pa + qd$. The average genetic effect of allele A1 (α_1) equals the deviation of the mean value of all possible genotypes that can be produced by gametes carrying the A1 allele from the population mean. The population mean has been derived earlier as $a(p - q) + 2pqd$ (1). The average effect of allele A1 is thus: $\alpha_1 = pa + qd - [a(p - q) + 2pqd] = q[a + d(q - p)]$. Similarly, the average effect of the A2 allele is $\alpha_2 = pd - qa - [a(p - q) + 2pqd] = -p[a + d(q - p)]$. $\alpha_1 - \alpha_2$ is known as α or the average effect of gene substitution. If there is no dominance, $\alpha_1 = qa$ and $\alpha_2 = -pa$, and the average effect of gene substitution α thus equals the genotypic value a ($\alpha = \alpha_1 - \alpha_2 = qa + pa = (q + p)a = a$).

The *breeding value* of an individual equals the sum of the average effects of gene substitution of an individual's alleles, and is therefore directly related to the mean genetic value of its offspring. Thus, the breeding value for an individual with genotype A1A1 is $2\alpha_1$ (or $2q\alpha$), for individuals with genotype A1A2 it is $\alpha_1 + \alpha_2$ (or $(q - p)\alpha$), and for individuals with genotype A2A2 it is $2\alpha_2$ (or $-2p\alpha$).

The breeding value is usually referred to as the *additive effect* of an allele (note that it includes both the values a and d), and differences between the genotypic effects (in terms of a , d , and $-a$, for genotypes A1A1, A1A2, A2A2 respectively) and the breeding values ($2q\alpha$, $(q - p)\alpha$, $-2p\alpha$, for genotypes A1A1, A1A2, A2A2 respectively) reflect the presence of dominance. Obviously, breeding values are of utmost importance to animal and crop breeders in determining which crossing will produce offspring with the highest milk yield, the fastest race horse, or the largest tomatoes.

Genetic Variance

Although until now we have ignored environmental effects, quantitative geneticists assume that populationwise the phenotype (P) is a function of both genetic (G) and environmental effects (E): $P = G + E$, where E refers to the environmental deviations, which have an expected average value of zero. By excluding the term $G \times E$, we assume no interaction between the genetic effects and the environmental effects (see **Gene-Environment Interaction**). If we also assume there is no covariance between G and E , the variance of the phenotype is given by $V_P = V_G + V_E$, where V_G represents the variance of the genotypic values of all contributing loci including both additive and nonadditive components, and V_E represents the variance of the environmental deviations. Statistically, the total genetic variance (V_G) can be obtained by applying the standard formula for the variance: $\sigma^2 = \sum f_i(x_i - \mu)^2$, where f_i denotes the frequency of genotype i , x_i denotes the corresponding genotypic mean of that genotype, and μ denotes the population mean, as calculated in (1). Thus, $V_G = p^2[a - (a(p - q) + 2pqd)]^2 + 2pq[d - (a(p - q) + 2pqd)]^2 + q^2[-a - (a(p - q) + 2pqd)]^2$. This can be simplified to $V_G = p^2[2q(a - dp)]^2 + 2pq[a(q - p) + d(1 - 2pq)]^2 + q^2[-2p(a + dq)]^2$, and further simplified to $V_G = 2pq[a + d(q - p)]^2 + (2pqd)^2 = V_A + V_D$ [3].

4 Additive Genetic Variance

If the phenotypic value of the heterozygous genotype lies midway between A1A1 and A2A2, the total genetic variance simplifies to $2pqa^2$. If d is not equal to zero, the ‘additive’ genetic variance component contains the effect of d . Even if $a = 0$, V_A is usually greater than zero (except when $p = q$). Thus, although V_A represents the variance due to the additive influences, it is not only a function of p , q , and a but also of d . Formally, V_A represents the variance of the breeding values, when these are expressed in terms of deviations from the population mean. The consequences are that, except in the rare situation in which all contributing loci are diallelic with $p = q$ and $a = 0$, V_A is usually greater than zero. Models that decompose the phenotypic variance into components of V_D , without including V_A , are therefore biologically implausible. When more than one locus is involved and it is assumed that the effects of these loci are uncorrelated and there is no interaction (i.e., no **epistasis**), the V_G ’s of each individual locus may be summed to obtain the total genetic variances of all loci that influence a trait [4, 5].

In most human quantitative genetic models, the observed variance of a trait is not modeled directly as a function of p , q , a , d , and environmental deviations (as all of these are usually unknown), but instead is modeled by comparing the observed resemblance between pairs of differential, known genetic

relatedness, such as monozygotic and dizygotic twin pairs (*see ACE Model*). Ultimately, p , q , a , d , and environmental deviations are the parameters that quantitative geneticists hope to ‘quantify’.

Additive Models

Although it may be found in the context of **experimental design** or **analysis of variance** (ANOVA) models, additivity or additive models is most commonly found in discussions of results from **multiple linear regression** analyses. Figure 1 is a reproduction of Cohen, Cohen, West, and Aiken's [1] graphical illustration of an additive model versus the same model but with an interaction present between their fictitious independent variables, X and Z , within the context of regression. Simply stated, additive models are ones in which there is no interaction between the independent variables, and in the case of the present illustration, this is defined by the following equation:

$$\hat{Y} = b_1X + b_2Z + b_0, \quad (1)$$

where $\hat{Y}$ is the predicted value of the dependent variable, b_1 is the regression coefficient for estimating Y from X (i.e., the change in Y per unit change in X), and similarly b_2 is the regression coefficient for estimating Y from Z . The intercept, b_0 , is a constant value to make adjustments for differences between X and Y units, and Z and Y units. Cohen et al. [1] use the following values to illustrate additivity:

$$\hat{Y} = 0.2X + 0.6Z + 2. \quad (2)$$

The point is that the regression coefficient for each independent variable (predictor) is constant over all values of the other independent variables in the model. Cohen et al. [1] illustrated this constancy using the example in Figure 1(a). The darkened lines in Figure 1(a) represent the regression of Y on X at each of three values of Z , two, five, and eight. Substituting the values in (2) for X (2, 4, 6, 8 and

Figure 1 Additive versus interactive effects in regression contexts. Used with permission: Figure 7.1.1, p. 259 of Cohen, J., Cohen, P., West, S.G. & Aiken, L.S. (2003). *Applied Multiple Regression/Correlation Analysis for the Behavioral Sciences*, 3rd Edition, Lawrence Erlbaum, Mahwah

2 Additive Models

10) along each of three values of Z will produce the darkened lines. These lines are parallel meaning that the regression of Y on X is constant over the values of Z . One may demonstrate this as well by holding values of X to two, five, and eight, and substituting all of the values of Z into (2). The only aspect of Figure 1(a) that varies is the height of the regression lines. There is a general upward displacement of the lines as Z increases.

Figure 1(b) is offered as a contrast. In this case, X and Z are presumed to have an interaction or joint effect that is above any additive effect of the variables. This is represented generally by

$$\hat{Y} = b_1X + b_2Z + b_3XZ + b_0 \quad (3)$$

and specifically for purposes of the illustration by

$$\hat{Y} = 0.2X + 0.6Z + 0.4XZ + 2. \quad (4)$$

Applying the same exercise used in (2) above would result in Figure 1(b). The point is that the regression of Y on X is not constant over the values of Z (and neither would the regression of Y on Z at values of X), but depends very much on the value of Z at which the regression of Y on X is calculated. This conditional effect is illustrated in Figure 1(b) by the angle of the plane representing the predicted values of Y at the joint of X and Z values.

As noted above, additive models are also considered in the context of experimental designs but much less frequently. The issue is exactly the same as in multiple regression, and is illustrated nicely by Charles Schmidt's graph which is reproduced in Figure 2. The major point of Figure 2 is that when there is no interaction between the independent variables (A and B in the figure), the main effects (additive effects) of each independent variable may be

Additivity assumption			
$R_{ij} = w_a a_i + w_b b_j$			
Example for a 2×2 design			
	A_1	A_2	$A_1 B_j - A_2 B_j$
B_1	$w_a a_1 + w_b b_1$	$w_a a_2 + w_b b_1$	$w_a(a_1 - a_2)$
B_2	$w_a a_1 + w_b b_2$	$w_a a_2 + w_b b_2$	$w_a(a_1 - a_2)$
	$w_b(b_1 - b_2)$	$w_b(b_1 - b_2)$	0
	$A_i B_1 - A_i B_2$		

Non-additivity assumption			
$R_{ij} = w_a a_i + w_b b_j + f(a_i, b_j)$			
Example for a 2×2 design			
	A_1	A_2	$A_1 B_j - A_2 B_j$
B_1	$w_a a_1 + w_b b_1 + f(a_1, b_1)$	$w_a a_2 + w_b b_1 + f(a_2, b_1)$	$w_a(a_1 - a_2) + [f(a_1, b_1) - f(a_2, b_1)]$
B_2	$w_a a_1 + w_b b_2 + f(a_1, b_2)$	$w_a a_2 + w_b b_2 + f(a_2, b_2)$	$w_a(a_1 - a_2) + [f(a_1, b_2) - f(a_2, b_2)]$
	$w_b(b_1 - b_2) + [f(a_1, b_1) - f(a_1, b_2)] - f(a_2, b_2)$	$w_b(b_1 - b_2) + [f(a_2, b_1) - f(a_2, b_2)]$	$[f(a_1, b_1) + f(a_2, b_2)] - [f(a_2, b_1) + f(a_1, b_2)]$
	$A_i B_1 - A_i B_2$

independently determined (shown in the top half of Figure 2). If, however, there is an interaction between the independent variables, then this joint effect needs to be accounted for in the analysis (illustrated by the gray components in the bottom half of Figure 2).

Additive Tree

Additive trees (also known as *path-length trees*) are often used to represent the proximities among a set of objects (see **Proximity Measures**). For example, Figure 1 shows an additive tree representing the similarities among seven Indo-European languages. The modeled proximities are the percentages of cognate terms between each pair of languages based on example data from Atkinson and Gray [1]. The additive tree gives a visual representation of the pattern of proximities, in which very similar languages are represented as neighbors in the tree.

Formally, an additive tree is a weighted tree graph, that is, a connected graph without cycles in which each arc is associated with a weight. In an additive tree, the weights represent the length of each arc. Additive trees are sometimes known as path-length trees, because the distance between any two points in an additive tree can be expressed as the sum of the lengths of the arcs in the (unique) path connecting the two points. For example, the tree distance between ‘English’ and ‘Swedish’ in Figure 1 is given by the sum of the lengths of the horizontal arcs in the path connecting them (the vertical lines in the diagram are merely to connect the tree arcs).

Distances in an additive tree satisfy the condition known as the *additive tree inequality*. This condition states that for any four objects a , b , c , and e ,

$$d(a, b) + d(c, e) \leq \max\{d(a, c) + d(b, e), d(a, e) + d(b, c)\}$$

Figure 1 An additive tree representing the percentage of shared cognates between each pair of languages, for sample data on seven Indo-European languages

Alternatively, the condition may be stated as follows: if x and y , and u and v are relative neighbors in the tree (as in Figure 2(a)), then the six distances must satisfy the inequality

$$\begin{aligned} d(x, y) + d(u, v) &\leq d(x, u) + d(y, v) \\ &= d(x, v) + d(y, u). \end{aligned} \quad (1)$$

If the above inequality is restricted to be a double equality, the tree would have the degenerate structure shown in Figure 2(b). This structure is sometimes called a ‘bush’ or a ‘star’. The additive tree structure is very flexible and can represent even a one-dimensional structure (i.e., a line) as well as those in Figure 2 (as can be seen by imagining that the leaf arcs for objects x and v in Figure 2(a) shrank to zero length). The length of a leaf arc in an additive tree can represent how typical or atypical an object is within its cluster or within the entire set of objects. For example, objects x and v in Figure 2(a) are more typical (i.e., similar to other objects in the set) than are u and y .

The additive trees in Figure 2 are displayed in an unrooted form. In contrast, the additive tree in Figure 1 is displayed in a rooted form – that is, one point in the graph is picked, arbitrarily or otherwise, and that point is displayed as the leftmost point in the graph. Changing the root of an additive tree can change the apparent grouping of objects into clusters, hence the interpretation of the tree structure.

When additive trees are used to model behavioral data, which contains error as well as true structure, typically the best-fitting tree is sought. That is, a tree structure is sought such that distances in the tree approximate as closely as possible (usually in a least-squares sense) the observed dissimilarities among the modeled objects. Methods for fitting additive trees to errorful data

Figure 2 Two additive trees on four objects, displayed in unrooted form

2 Additive Tree

include those described in [2–6] and [7], the last method using a **maximum-likelihood** approach. A public-domain software program for fitting additive trees, GTREE [3], may be obtained at several sites, including <http://www.netlib.org/mds/> or <http://www.columbia.edu/~jec34/>. Routines implementing the algorithm of Hubert and Arabie [5] are also available (*see* http://ljhoff.psych.uiuc.edu/cda_toolbox/cda_toolbox_manual.pdf).

Additivity Tests

When a test of additivity is performed on a set of data, the null hypothesis that a dependent variable is an additive, noninteractive function of two (or more) independent variables and the alternative hypothesis of nonadditivity are characterized by one or more interactions between the independent variables. If the dependent variable is on a quantitative (interval or ratio) scale (*see Measurement: Overview*), it is possible to perform a test of additivity in the context of **analysis of variance** (ANOVA). A more general test of additivity is achieved in the context of additive conjoint measurement theory. According to this theory, in order for additivity to hold on some monotonic transformation of the dependent variable, such that combinations of the independent variables are measurable on a common interval scale, it is necessary for data to be consistent with a hierarchy of (qualitative) cancellation axioms. The following two sections describe tests of additivity that are based on ANOVA and additive conjoint measurement, respectively.

Testing for Additivity, Assuming Quantitative Measurement

Suppose that IJ exchangeable sequences $\{Y_{1ij}, \dots, Y_{nij}, \dots, Y_{Nij}; i = 1, \dots, I, j = 1, \dots, J\}$ of data are observed from a two-factor experimental design, where Y_{nij} refers to the n th observation of a quantitative dependent variable in cell ij , corresponding to a level $i \in \{1, \dots, I\}$ of one independent variable and level $j \in \{1, \dots, J\}$ of a second independent variable. It is natural to model such data by a two-way ANOVA, given by

$$Y_{nij} = \mu + \alpha_i + \beta_j + \gamma_{ij} + \varepsilon_{nij} \quad (1)$$

for all levels $i = 1, \dots, I$ and $j = 1, \dots, J$, where μ is the grand mean of the dependent variable, the population parameter α_i represents the main effect of level i , the parameter β_j is the main effect of level j , the parameter γ_{ij} is the interaction effect of levels i and j , and ε_{nij} is error assumed to be a random sample from a $N(0, \sigma_{\text{Error}}^2)$ normal distribution (*see Analysis of Variance; Multiple Linear Regression;*

Repeated Measures Analysis of Variance). In an ANOVA, the well-known F -statistic

$$F_{\text{Int}} = \frac{\sigma_{\text{Int}}^2}{\sigma_{\text{Error}}^2} = \frac{SS_{\text{Int}}/df_{\text{Int}}}{SS_{\text{Error}}/df_{\text{Error}}} \quad (2)$$

provides a test of the null hypothesis of additivity $H_0: \{\gamma_{ij} = 0, \forall i, j\}$ versus the alternative hypothesis of nonadditivity $H_1: \{\gamma_{ij} \neq 0, \text{ for some } i, j\}$. Under H_0 , statistic (2) follows an F distribution with $\{df_{\text{Int}}, df_{\text{Error}}\}$ degrees of freedom, where σ_{Int}^2 and SS_{Int} are the variance and sums-of-squares due to interaction, respectively, and SS_{Error} is the error sums-of-squares (e.g., [34]) (*see Catalogue of Probability Density Functions*). Under a chosen Type I error rate, the additive null hypothesis is rejected when the value of F_{Int} is unusually large. The F test (2) can be extended to test for interactions between three or more independent variables, and/or to test for interactions in two or more dependent variables (*see Multivariate Analysis of Variance*). Also, there are alternative tests of additivity, such as those [2, 3] based on the rank of the interaction matrix $\gamma = (\gamma_{ij})$, as well as distribution-free tests.

When there is exactly one observation per cell ij , the ANOVA model is saturated, with zero degrees of freedom left ($df_{\text{Error}} = 0$) to perform the F test of additivity. To circumvent a saturated model, several researchers have proposed testing the additivity hypothesis $H_0: \{\gamma_{ij} = 0, \forall i, j\}$, by restricting each of the interaction parameters (*see Interaction Effects*) by some specific function, under the nonadditive alternative hypothesis H_1 [7, 10, 11, 18, 22–25, 27, 28, 33, 35, 36]. For example, Tukey [36, 33] proposed testing $H_1: \{\gamma_{ij} = \lambda\alpha_i\beta_j \neq 0, \text{ some } i, j\}$, while Johnson and Graybill [11] proposed $H_1: \{\gamma_{ij} = \lambda\delta_i\xi_j \neq 0, \text{ some } i, j\}$, where the so-called ‘free’ parameters λ , δ_i , and ξ_j represent sources of interaction that are not due to main effects. Alternatively, Tusell [37] and Boik [4,5] proposed tests of additivity that do not require the data analyst to assume any particular functional form of interaction, and, in fact, they are sensitive in detecting many forms of nonadditivity [6].

Testing for Additivity, without Assuming Quantitative Measurement

Let an element of a (nonempty) product set $ax \in A_1 \times A_2$ denote the dependent variable that results

2 Additivity Tests

after combining the effect of level $a \in A_1 = \{a, b, c, \dots\}$ from one independent variable, and the effects of level $x \in A_2 = \{x, y, z, \dots\}$ from another independent variable. According to the theory of additive conjoint measurement [20], the effects of two independent variables are additive if and only if

$$ax \succsim by \text{ implies } f_1(a) + f_2(x) \geq f_1(b) + f_2(y) \quad (3)$$

holds for all $ax, by \in A_1 \times A_2$, where $\succsim$ denotes a weak order, and the functions f_1 and f_2 map the observed effects of the independent variables onto interval scales. In order for the additive representation (3) to hold for some monotonic transformation of the dependent variable, a hierarchy of cancellation axioms must be satisfied [17, 20, 26]. For example, single cancellation (often called order-independence) is satisfied when

$$ax \succsim bx \text{ if and only if } ay \succsim by \quad (4a)$$

$$ax \succsim ay \text{ if and only if } bx \succsim by \quad (4b)$$

hold for all $a, b \in A_1$ and all $x, y \in A_2$. Double cancellation is satisfied when

$$ay \succsim bx \text{ and } bz \succsim cy \text{ implies } az \succsim cx \quad (5)$$

holds for all $a, b, c \in A_1$ and all $x, y, z \in A_2$. The additive representation (3) and cancellation axioms can be extended to any number of independent variables [17], and, of course, an additive representation is unnecessary when all independent variables have zero effects.

In evaluating the fit of data to the cancellation axioms, many researchers have either counted the number of axiom violations or employed multiple nonparametric test statistics (e.g., [8, 9, 19, 26, 29–31, 38]) (see **Binomial Confidence Interval; Binomial Distribution; Estimating and Testing Parameters; Median; Kendall's Coefficient of Concordance; Kendall's Tau – τ**). Unfortunately, such approaches to testing additivity are not fully satisfactory. They assume that different tests of cancellation are statistically independent, which they are not. Also, as is well-known, the Type I error rate quickly increases with the number of statistical tests performed.

These statistical issues are addressed with a model-based approach to testing cancellation axioms. Suppose that $\{Y_{1k}, \dots, Y_{n_k}, \dots, Y_{N_k}; k = 1, \dots, m\}$

are m exchangeable sequences of N_k observations of a dependent variable, where Y is either a real-valued scalar or vector, and each sequence arises from some experimental condition $k \in \{1, \dots, m\}$. For example, $m = IJ$ conditions may be considered in a two-factor experimental design. According to **de Finetti's** representation theorem (e.g., [1]), the following Bayesian model describes the joint probability of m exchangeable sequences:

$$\begin{aligned} p(Y_{1k}, \dots, Y_{n_k}, \dots, Y_{N_k}; k = 1, \dots, m) \\ = \int_{\Theta \subseteq \Omega} \prod_{k=1}^m \prod_{n_k=1}^{N_k} p(Y_{n_k} | \Theta_k) p(\Theta_1, \dots, \Theta_k, \dots, \Theta_m) \\ \times d\Theta_1, \dots, \Theta_k, \dots, \Theta_m, \end{aligned} \quad (6)$$

where $p(Y_{n_k} | \Theta_k)$ is the sampling likelihood at data point Y_{n_k} given the k th population parameter Θ_k , and $p(\Theta_1, \dots, \Theta_k, \dots, \Theta_m)$ is the prior distribution over the parameter vector $\Theta = (\Theta_1, \dots, \Theta_k, \dots, \Theta_m)$ (see **Bayesian Statistics**). The notation $\Theta \subseteq \Omega$ refers to the fact that any set of cancellation axioms implies order-restrictions on the dependent variable (as shown in (4) and (5)), such that the parameter vector Θ is constrained to lie within a proper subset Ω of its total parameter space. The form of the constraint Ω depends on the set of cancellation axioms under consideration. A test of a set of cancellation axioms is achieved by testing the fit of a set of data $\{Y_{1k}, \dots, Y_{n_k}, \dots, Y_{N_k}; k = 1, \dots, m\}$ to the model in (6).

Karabatsos [12, 15, 16] implemented this approach for testing several cancellation axioms, in the case where, for $k = 1, \dots, m$, the dependent variable is dichotomous $Y_{n_k} \in \{0, 1\}$ and Θ_k is a binomial parameter. For example, Karabatsos [12] tested single cancellation (4) by evaluating the fit of dichotomous data $\{Y_{1k}, \dots, Y_{n_k}, \dots, Y_{N_k}; k = 1, \dots, m\}$ to the model in (6), where all $m = IJ$ binomial parameters were subject to the constraint Ω that $\Theta_{ij} \leq \Theta_{i+1,j}$ for all ordered levels $i = 1, \dots, I - 1$ of the first independent variable and $\Theta_{ij} \leq \Theta_{i,j+1}$ for all ordered levels $j = 1, \dots, J - 1$ of the second independent variable.

Karabatsos [14] later generalized this binomial approach, by considering a vector of multinomial parameters $\Theta_k = (\theta_{1k}, \dots, \theta_{rk}, \dots, \theta_{Rk})$ for each experimental condition $k = 1, \dots, m$, where θ_{rk} refers to the probability of the r th response pattern. Each response pattern is characterized by a particular

weak order defined over all elements of $A_1 \times A_2$. In this context, Ω refers to the sum-constraint $\sum_{r_k \in \sim V_k} \theta_{rk} \geq C$ for each experimental condition k , and some chosen threshold $C \in [1/2, 1]$, where $\sim V_k$ is the set of response patterns that do not violate a given cancellation axiom.

Karabatsos [13] proposed a slightly different multinomial model, as a basis for a Bayesian bootstrap [32] approach to isotonic (inequality-constrained) regression (see **Bootstrap Inference**). This procedure can be used to estimate the non-parametric posterior distribution of a discrete- or continuous-valued dependent variable Y , subject to the order-constraints of the set of all possible linear orders (for example, $Y_1 \leq Y_2 \leq \dots \leq Y_k \leq \dots \leq Y_m$) that satisfy the *entire hierarchy* of cancellation axioms. Here, a test of additivity is achieved by evaluating the fit of the observed data $\{Y_{1k}, \dots, Y_{nk}, \dots, Y_{Nk}; k = 1, \dots, m\}$ to the corresponding order-constrained posterior distribution of Y .

Earlier, as a non-Bayesian approach to additivity testing, Macdonald [21] proposed isotonic regression to determine the least-squares **maximum-likelihood estimate** (MLE) of the dependent variable $\{\hat{Y}_k; k = 1, \dots, m\}$, subject to a linear order-constraint (e.g., $Y_1 \leq Y_2 \leq \dots \leq Y_k \leq \dots \leq Y_m$) that satisfies a given cancellation axiom (see **Least Squares Estimation**). He advocated testing each cancellation axiom separately, by evaluating the fit of the observed data $\{Y_{1k}, \dots, Y_{nk}, \dots, Y_{Nk}; k = 1, \dots, m\}$ to the MLE $\{\hat{Y}_k; k = 1, \dots, m\}$ under the corresponding axiom.

Adoption Studies

Adoption usually refers to the rearing of a nonbiological child in a family. This practice is commonplace after wars, which leave many children orphaned, and is moderately frequent in peacetime. Approximately 2% of US citizens are adoptees.

Historically, adoption studies have played a prominent role in the assessment of genetic variation in human and animal traits [10]. Most early studies focused on cognitive abilities [9], but there is now greater emphasis on psychopathology [5] and physical characteristics, such as body mass [20]. Adoption studies have made major substantive contributions to these areas, identifying the effects of genetic factors where they were previously thought to be absent [3, 12, 15].

In recent years, the adoption study has been overshadowed by the much more popular twin study [17] (*see Twin Designs*). Part of this shift may be due to the convenience of twin studies and the complex ethical and legal issues involved in the ascertainment and sampling of adoptees. Certain Scandinavian countries – especially Denmark, Sweden, and Finland [8, 13, 14] – maintain centralized databases of adoptions, and, thus, have been able to mount more representative and larger adoption studies than elsewhere.

The adoption study is a ‘natural experiment’ that mirrors cross-fostering designs used in genetic studies of animals, and, therefore, has a high face validity as a method to resolve the effects of genes and environment on individual differences. Unfortunately, the adoption study also has many methodological difficulties. First is the need to maintain confidentiality, which can be a problem even at initial ascertainment, as some adoptees do not know that they are adopted. Recent legal battles for custody fought between biological and adoptive parents make this a more critical issue than ever. Secondly, in many substantive areas, for example, psychopathology, there are problems with sampling, in that neither the biological nor the adoptive parents can be assumed to be a random sample of parents in the population. For example, poverty and its sequel may be more common among biological parents who have their children adopted into other families than among parents who rear their children themselves. Conversely, prospective adoptive parents are, on average, and through self-selection, older and less fertile than biological parents. In addition, they

are often carefully screened by adoption agencies, and may be of higher socioeconomic status than nonadoptive parents. Statistical methods (see below) may be used to control for these sampling biases if a random sample of parents is available. Some studies indicate that adoptive and biological parents are quite representative of the general population for demographic characteristics and cognitive abilities [19], so this potential source of bias may not have substantially affected study results.

Thirdly, selective placement is a common methodological difficulty. For statistical purposes, the ideal adoption study would have randomly selected adoptees placed at random into randomly selected families in the population. Often, there is a partial **matching** of the characteristics of the adoptee (e.g., hair and eye color, religion and ethnicity) to those of the adopting family. This common practice may improve the chances of successful adoption. Statistically, it is necessary to control for the matching as far as possible. Ideally, the matching characteristics used should be recorded and modeled. Usually, such detailed information is not available, so matching is assumed to be based on the variables being studied and modeled accordingly (see below). In modern adoption studies, these methods are used often [18, 19].

Types of Adoption Study

Nuclear families in which at least one member is not biologically related to the others offer a number of potential comparisons that can be genetically informative (see Table 1). Of special note are monozygotic (MZ) twins reared apart (MZ_A). Placed into uncorrelated environments, the correlation between MZ twins directly estimates the proportion of variation due to all genetic sources of variance (‘broad **heritability**’). Estimation of heritability in this way is statistically much more powerful than, for example, the classical twin study that compares MZ and dizygotic (DZ) twins reared together (MZ_T and DZ_T). With MZ_A twins, the test for heritability is a test of the null hypothesis that the correlation is zero, whereas the comparison of MZ_T and DZ_T is a test of a difference between correlations (*see Correlation Issues in Genetics Research*). Environmental effects shared by members of a twin pair (known as ‘common’, ‘shared’ or ‘family’ environment or ‘C’) are excluded by design. If this source of variation is of

2 Adoption Studies

Table 1 Coefficients of genetic and environmental variance components quantifying resemblance between adopted and biological relatives, assuming random sampling, mating and placement

Relationship	Variance component						
	V_A	V_D	V_{AA}	V_{AD}	V_{DD}	E_S	E_P
BP-BC	$\frac{1}{2}$	0	$\frac{1}{4}$	0	0	0	1
BP-AC	$\frac{1}{2}$	0	$\frac{1}{4}$	0	0	0	0
AP-AC	0	0	0	0	0	0	1
AC-BC	0	0	0	0	0	1	0
BC-BC _T	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{8}$	$\frac{1}{16}$	1	0
BC-BC _A	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{8}$	$\frac{1}{16}$	0	0
MZ _T -MZ _T	1	1	1	1	1	1	0
MZ _A -MZ _A	1	1	1	1	1	0	0

Note: V_A – additive genetic; V_D – dominance genetic; V_{AA} – additive $\times$ additive interaction; V_{AD} – additive $\times$ dominance interaction; V_{DD} – dominance $\times$ dominance interaction; E_S – environment shared by siblings; E_P – environment shared or transmitted between parent and child. Relationships are: MZ – monozygotic twin; DZ – dizygotic twin; BP – biological parent; BC – biological child; AP – adoptive parent; AC – adopted child. The subscripts T and A refer to reared together and reared apart, respectively.

interest, then additional groups of relatives, such as unrelated individuals reared together, are needed to estimate it. Similar arguments may be made about across-generational sources of resemblance. Heath and Eaves [11] compared the power to detect genetic and environmental transmission across several twin-family (twins and their parents or twins and their children) adoption designs.

Methods of Analysis

Most modern adoption study data are analyzed with **Structural Equation Models** (SEM) [2, 17]. SEM is an extension of **multiple linear regression** analysis that involves two types of variable: *observed variables* that have been measured, and **latent variables** that have not. Two variables may be specified as causally related or simply correlated from unspecified effects. It is common practice to represent the variables and their relationships in a path diagram (see **Path Analysis and Path Diagrams**), where single-headed arrows indicate causal relationships, and double-headed arrows represent correlations. By convention, observed variables are shown as squares and latent variables are shown as circles.

Figure 1 shows the genetic and environmental transmission from biological and adoptive parents to

three children. Two of the children are offspring of the biological parents (siblings reared together), while the third is adopted. This diagram may also be considered as multivariate, allowing for the joint analysis of multiple traits. Each box and circle then represents a vector of observed variables. Multivariate analyses (see **Multivariate Analysis: Overview**) are particularly important when studying the relationship between parental attributes and outcomes in their offspring. For example, harsh parenting may lead to psychiatric disorders. Both variables should be studied in a multivariate genetically informative design such as an adoption or twin study to distinguish between the possible direct and indirect genetic and environmental pathways.

From the rules of path analysis [22, 23] we can derive predicted covariances among the relatives in terms of the parameters of the model in Figure 1. These expectations may, in turn, be used in a structural equation modeling program such as Mx [16] (see **Software for Behavioral Genetics**) to estimate the parameters using **maximum likelihood** or some other goodness-of-fit function. Often, simpler models than the one shown will be adequate to account for a particular set of data.

A special feature of the diagram in Figure 1 is the dotted lines representing delta-paths [21].

Figure 1 Path diagram showing sources of variation and covariance between: adoptive mother, AM; adoptive father, AF; their own biological children, BC_1 and BC_2 ; a child adopted into their family, AC_1 ; and the adopted child's biological parents, BF and BM

These represent the effects of two possible types of selection: assortative mating, in which husband and wife correlate; and selective placement, in which the adoptive and biological parents are not paired at random. The effects of these processes may be deduced from the Pearson–Aitken selection formulas [1]. These formulas are derived from linear regression under the assumptions of multivariate linearity and homoscedasticity. If we partition the variables into selected variables, X_S , and unselected variables X_N , then it can be shown that changes in the covariance of X_S lead to changes in covariances among X_N and the cross-covariances (X_S with X_N). Let the original (preselection) covariance matrix of X_S be $\mathbf{A}$, the original covariance matrix of X_N be $\mathbf{C}$, and the covariance between X_N and X_S be $\mathbf{B}$. The preselection matrix may be written

$$\left(\begin{array}{c|c} \mathbf{A} & \mathbf{B} \\ \hline \mathbf{B}' & \mathbf{C} \end{array} \right).$$

If selection transforms $\mathbf{A}$ to $\mathbf{D}$, then the new covariance matrix is given by

$$\left(\begin{array}{c|c} \mathbf{D} & \mathbf{DA}^{-1}\mathbf{B} \\ \hline \mathbf{B}'\mathbf{A}^{-1}\mathbf{D} & \mathbf{C} - \mathbf{B}'(\mathbf{A}^{-1} - \mathbf{A}^{-1}\mathbf{DA}^{-1})\mathbf{B} \end{array} \right).$$

Similarly, if the original means are $(\mathbf{x}_S; \mathbf{x}_N)'$ and selection modifies $\mathbf{x}_S$ to $\tilde{\mathbf{x}}_S$, then the vector of means after selection is given by

$$[\mathbf{x}_S; \mathbf{x}_N + \mathbf{A}^{-1}\mathbf{B}(\mathbf{x}_S - \tilde{\mathbf{x}}_S)]'.$$

These formulas can be applied to the covariance structure of all the variables in Figure 1. First, the formulas are applied to derive the effects of assortative mating, and, secondly, they are applied to derive the effects of selective placement. In both cases, only the covariances are affected, not the means. An interesting third possibility would be to control for the effects of nonrandom selection of the

biological and adoptive relatives, which may well change both the means and the covariances.

Selected Samples

A common approach in adoption studies is to identify members of adoptive families who have a particular disorder, and then examine the rates of this disorder in their relatives. These rates are compared with those from control samples. Two common starting points for this type of study are (a) the adoptees (the adoptees' families method), and (b) the biological parents (the adoptees study method). For rare disorders, this use of selected samples may be the only practical way to assess the impact of genetic and environmental factors.

One limitation of this type of method is that it focuses on one disorder, and is of limited use for examining **comorbidity** between disorders. This limitation is in contrast to the population-based sampling approach, where many characteristics – and their covariances or comorbidity – can be explored simultaneously.

A second methodological difficulty is that ascertained samples of the disordered adoptees or parents may not be representative of the population. For example, those attending a clinic may be more severe or have different risk factors than those in the general population who also meet criteria for diagnosis, but do not attend the clinic.

Genotype × Environment Interaction

The natural experiment of an adoption study provides a straightforward way to test for **gene–environment interaction**. In the case of a continuous phenotype, interaction may be detected with linear regression on

1. the mean of the biological parents' phenotypes (which directly estimates heritability)
2. the mean of the adoptive parents' phenotypes
3. the product of points 1 and 2.

Significance of the third term would indicate significant $G \times E$ interaction. With binary data such as psychiatric diagnoses, the rate in adoptees may be compared between subjects with biological or adoptive parents affected, versus both affected. $G \times E$

interaction has been found for alcoholism [7] and substance abuse [6].

Logistic regression is a popular method to test for genetic and environmental effects and their interaction on binary outcomes such as psychiatric diagnoses. These analyses lack the precision that structural equation modeling can bring to testing and quantifying specific hypotheses, but offer a practical method of analysis for binary data. Analysis of binary data can be difficult within the framework of SEM, requiring either very large sample sizes for asymptotic weighted least squares [4], or integration of the multivariate normal distribution (*see Catalogue of Probability Density Functions*) over as many dimensions as there are relatives in the pedigree, which is numerically intensive.

Age–Period–Cohort Analysis

To determine the effect of time on a particular outcome for an individual, it is essential to understand the relevant temporal perspective. Age affects many aspects of life, including the risk of disease, so this is an essential component of any analysis of time trends. Period denotes the date of the outcome, and if the outcome varies with period it is likely due to some underlying factor that affects the outcome, and varies in the same way for the entire population regardless of age. Cohort, on the other hand, refers to generational effects caused by factors that only affect particular age groups when the level of the factor changes with time.

An example of a period effect would be the potential influence of an air contaminant that affected all age groups in the same way. If the level of exposure to that factor increased/decreased with time, exerting a change in the outcome in all age groups, then we would expect a related pattern across all age groups in the study. In studies that take place over long periods of time, the technology for measuring the outcome may change, giving rise to an artifactual effect that was not due to change in exposure to a causative agent. For example, intensive screening for disease can identify disease cases that would not previously have been identified, thus artificially increasing the disease rate in a population that has had no change in exposure over time (*see Cohort Studies*).

Cohort, sometimes called *birth cohort*, effects may be due to factors related to exposures associated with the date of birth, such as the introduction of a particular drug or practice during pregnancy. For example, a pregnancy practice associated with increased disease risk and adopted by the population of mothers during a particular time period could affect the risk during the life span of the entire generation born during that period. While it is common to refer to these effects as being associated with year of birth, they could also be the result of changes in exposure that occurred after birth. In many individuals, lifestyle factors tend to become fixed as their generation approaches adulthood. The quantification of these generational effects is referred to as *cohort effects*. To illustrate, consider a study of trends in suicide

rates in Japan which discovered that the generation of men who enlisted to fight in World War II had a lifelong increased risk of suicide when compared to other generations [6]. Presumably, these generational trends were due to experiences well after birth.

As an example of the alternative temporal perspectives, consider the birth rate, that is, the average number of births in a year per 1000 women for blacks by age during the period 1980–2002. These are analyzed for five-year age and period intervals. The final period only covers the years 2000–2002 because more recent data were not available, but we will assume that these rates are representative of the rates for 2000–2004. Figure 1 shows a graph of the age trends in the birth rates for each of the periods, and the vertical axis employs a log scale. The rate for a given age interval is plotted in the center of that interval (e.g., the point at age = 17.5 represents the interval from 15 to 20). A cohort may be identified for each age-period (age interval 15–20 and period interval 1980–1985), and the range in this case may be 10 years. For example, the earliest cohort for the first age-period would be someone nearly 20 at the beginning of 1980, who would have been born in 1960. The latest cohort would have just turned 15 at the end of 1984, and would have been born at the end of 1969. In general, the cohort interval is twice as long as the age and period intervals when the latter two are equal. In addition, the cohort intervals overlap, because the next cohort in our example would include individuals born from 1965 to 1974. Figure 2 shows a semilog plot of the age-specific birth rates for the different cohorts. A subtle difference between Figures 1 and 2 is that the segments in the cohort plot tend to be more nearly parallel, as can be seen in the lines connecting the rates for age 17.5 with 22.5. In the age-period-cohort modeling framework, the temporal factor that achieves the greatest degree of parallelism tends to be the predominant factor in the model, and this is identified in a more formal way by assessing statistical significance.

An inherent redundancy among these three temporal factors arises from the fact that knowing any two factors implies the value of the third. For example, if we know an individual's age (a) at a given date or period (p), then the cohort is the difference, ($c = p - a$). This linear dependence gives rise to an identifiability problem in a formal regression model that attempts to obtain quantitative estimates

Figure 1 Period plot: a semilog plot of birth rates among US black women by age and period

of regression parameters associated with each temporal element. Suppose that the expected value of the outcome, Y (the log birth rate in our example) is linearly related to the temporal factors,

$$E[Y] = \beta_0 + a\beta_a + p\beta_p + c\beta_c. \quad (1)$$

Using the linear relationship between the temporal factors gives rise to

$$\begin{aligned} E[Y] &= \beta_0 + a\beta_a + p\beta_p + (p - a)\beta_c \\ &= \beta_0 + a(\beta_a - \beta_c) + p(\beta_p + \beta_c), \end{aligned} \quad (2)$$

which has only two identifiable parameters besides the intercept instead of the expected three. Another way of visualizing this phenomenon is that all combinations of age, period and cohort may be displayed in the Lexis diagram shown in Figure 3, which is obviously a representation of a two dimensional plane instead of the three dimensions expected for three separate factors.

In general, these analyses are not limited to linear effects applied to continuous measures of time, but instead they are applied to temporal intervals, such as mortality rates observed for five- or ten-year intervals

of age and period. When the widths of these intervals are equal, the model may be expressed as

$$E[Y_{ijk}] = \mu + \alpha_i + \pi_j + \gamma_k, \quad (3)$$

where μ is the intercept, α_i the effect of age for the i th ($i = 1, \dots, I$) interval, π_j the effect of period for the j th ($j = 1, \dots, J$) interval, and γ_k the effect of the k th cohort ($k = j - i + I = 1, \dots, K = I + J - 1$). The usual constraints in this model imply that $\sum \alpha_i = \sum \pi_j = \sum \gamma_k = 0$. The identifiability problem manifests itself through a single unidentifiable parameter [3], which can be more easily seen if we partition each temporal effect into components of overall linear trend, and curvature or departure from linear trend. For example, age can be given by $\alpha_i = i'\beta_\alpha + \tilde{\alpha}_i$, where $i' = i - 0.5(I + 1)$, β_α is the overall slope and $\tilde{\alpha}_i$ the curvature. The overall model can be expressed as

$$\begin{aligned} E[Y_{ijk}] &= \mu + (i'\beta_\alpha + \tilde{\alpha}_i) + (j'\beta_\pi + \tilde{\pi}_j) \\ &\quad + (k'\beta_\gamma + \tilde{\gamma}_k) \\ &= \mu + i'(\beta_\alpha - \beta_\gamma) + j'(\beta_\pi + \beta_\gamma) \\ &\quad + \tilde{\alpha}_i + \tilde{\pi}_j + \tilde{\gamma}_k, \end{aligned} \quad (4)$$

Figure 2 Cohort plot: a semilog plot of birth rates among US black women by age and cohort

Figure 3 Lexis diagram showing the relationship between age, period, and cohort. The diagonal line traces age-period lifetime for an individual born in 1947

4 Age–Period–Cohort Analysis

because $k' = j' - i'$. Thus, each of the curvatures can be uniquely determined, but the overall slopes are hopelessly entangled so that only certain combinations can be uniquely estimated [4].

The implication of the identifiability problem is that the overall direction of the effect for any of the three temporal components cannot be determined from a regression analysis (*see Multiple Linear Regression*). Thus, we cannot even determine whether the trends are increasing or decreasing with cohort, for instance. Figure 4 displays several combinations of age, period and cohort parameters, each set of which provides an identical set of fitted rates. However, even though the specific trends cannot be uniquely estimated, certain combinations of the overall trend can be uniquely determined, such as $\beta_\pi + \beta_\gamma$ which is called the *net drift* [1, 2]. Alternative drift estimates covering shorter time spans can also be determined, and these have practical significance in that they describe the experience of following a particular age group in time, because both period and cohort will advance together. Curvatures, on the other hand, are completely determined including polynomial parameters for the square and higher powers, changes in slopes, and second differences. The significance test for any one of the temporal effects in

the presence of the other two will generally be a test of the corresponding curvature, and not the slope. Holford provides further detail on how software can be set up for fitting these models [5].

To illustrate the implications of the identifiability problem, and the type of valid interpretations that one can make by fitting an age-period-cohort model, we return to the data on birth rates among US black women. There are seven five-year age groups and five periods of identical width thus yielding $7 + 5 - 1 = 11$ cohorts. A general linear model (*see Generalized Linear Models (GLM)*) will be fitted to the log rates, introducing main effects for age, period and cohort. In situations in which the numerator and denominator for the rate are available, it is common to fit a **log-linear model** using Poisson regression (*see Generalized Linear Models (GLM)*), but the resulting interpretation issue will be identical for either model. An F test for the effect of cohort in the presence of age and period yields a value of 26.60 with $df_1 = 9$ and $df_2 = 15$. The numerator degrees of freedom, df_1 , are not 10 because the model with age and period effects implicitly includes their linear contribution, and thus the linear contribution for cohort. Therefore, this test can only evaluate the curvature for cohort. Similarly, the tests for age

Figure 4 Age, period, and cohort effects for a log-linear model for birth rates in US black women, 1980–2001 by alternatively constrained period slopes

($F_{5,15} = 3397.47$, $p < 0.0001$) and period ($F_{3,15} = 4.50$, $p = 0.0192$) in the presence of the other two temporal factors are tests of curvature.

Figure 4 shows five sets of age, period and cohort parameters that may be obtained using least squares estimation. Each set of parameters provides an identical fit to the data, but there is obviously not a unique solution here but rather an infinite number of solutions. At the same time, once one of the slopes has been fixed (in this example the period slopes have been fixed), the other slopes can be identified. Notice that when the period slope is arbitrarily decreased, the underlying period trend is effectively rotated in a clockwise direction. Observing the corresponding cohort parameters, we can see that when the period trends are decreased, the trends for cohort are increased, that is, the corresponding estimates for the cohort parameters are rotated counterclockwise. Likewise, the age parameters experience a counterclockwise rotation, although in this example it is not easy to see because of the steep age trends. Sometimes there may be external information indicating a particular constraint for one of the temporal parameters, and once this can be applied then the other effects are also identified. However, such information must come from external sources because within the dataset itself it is impossible to disentangle the interrelationship so as to obtain a unique set of parameters.

In the absence of the detail required to make a constraint on one of the temporal parameters, it is safer to make inferences using estimable functions of the parameters, that is, functions that do not depend on an arbitrary constraint. Curvature, which would include both the overall departure from linear trend, as well as local changes of direction are estimable [1, 2, 4]. The latter would include polynomial terms of power greater than one (see **Polynomial Model**), change of slope, or second differences, which would compare the parameter at one point to the average of the parameters just before and just after that point. In addition, the sum of the period and cohort slope or drift is also estimable, thus providing a net indication of the trend.

In our example, we can see from the solid lines in Figure 4 that the first three periods show a gradual increasing trend, as do the first four cohorts. If we were to add these slopes, we would have an estimate of the early drift, which would be positive because both of the slope components are positive. Similarly,

the last three periods and the last three cohorts are negative, implying that the recent drift would also be negative. While the individual interpretation of the other lines shown in Figure 4 would be slightly different, the sum would be the same, thus indicating increasing early drift and decreasing late drift.

We can estimate the drift by taking the sum of the contrasts for linear trend in the first three periods and the first four cohorts, that is, $(-1, 0, 1, 0, 0)/2$ for period and $(-3, -1, 1, 3, 0, 0, 0, 0, 0)/10$ for cohort. This yields the result 0.1036 ($t_{15} = 6.33$, $p < 0.0001$), which indicates that the positive early drift is statistically significant. Similarly, the late drift, which uses the contrast $(0, 0, -1, 0, 1)/2$ for period and $(0, 0, 0, 0, 0, 0, -3, -1, 1, 3)/10$ for cohort, yields -0.1965 ($t_{15} = -12.02$, $p < 0.0001$), which is highly significant and negative.

In this discussion, we have concentrated on the analysis of data that have equal spaced intervals with age and period. The unequal case introduces further identifiability problems, which involve not only the overall linear trend, but certain short-term patterns, as well (see **Identification**). The latter can sometime appear to be cyclical trends; therefore, considerable care is needed in order to be certain that these are not just an artifact of the identifiability issues that arise for the unequal interval case.

Akaike's Criterion

Akaike's information criterion (AIC) is now probably best known as an overall goodness-of-fit index (GFI) for confirmatory factor (*see* **Factor Analysis: Confirmatory**) and **structural equation models (SEMs)**. Originally developed for model selection in regression models [3], AIC has a remarkably solid theoretical foundation in information theory in the mathematical statistics literature [1–4]. The problem of model selection for which AIC was formulated is that of choosing a ‘best approximating’ model among a class of competing models, possibly with different numbers of estimated parameters, using an appropriate statistical criterion. Conceptually, AIC does this by balancing what Bozdogan [4] refers to as the risk of modeling, the extent to which the fitted model differs from the true model in the population, versus the risk of estimation, or discrepancy between population model parameters and sample-based estimates (*see* [8]).

AIC is often written as:

$$\chi^2 + 2q \quad (1)$$

where χ^2 is the maximum likelihood chi-squared statistic and q refers to the number of free parameters being estimated in the estimated model. According to Bozdogan [3], ‘the first term ... is a measure of inaccuracy, badness of fit, or bias when the **maximum likelihood estimators** of the models are used’ while the ‘... second term ... is a measure of complexity, of the penalty due to the increased unreliability, or compensation for the bias in the first term which depends upon the number of parameters used to fit the data’ (p. 356). Thus, when several models’ parameters are estimated using maximum likelihood, the models’ AICs can be compared to find a model with a minimum value of AIC. ‘This procedure is called the *minimum AIC procedure* and the model with the minimum AIC is called the *minimum AIC estimate* (MAICE) and is chosen to be the best model’ ([3], p. 356). Cudeck and Browne [6] and Browne and Cudeck [5] considered AIC and a closely related index proposed by Schwartz [11] as measures of cross-validation of SEMs; Cudeck and Brown proposed a ‘rescaled’ version of AIC, ostensibly ‘to eliminate the effect of sample size’ (p. 154).

Also, Bozdogan [3, 4] has extended Akaike's theory to develop a number of information complexity (ICOMP) measures of model fit based on various definitions of model complexity.

In one large-scale simulation, Marsh, Balla, and McDonald [9] found that AIC was very sensitive to sample size (an undesirable characteristic for a GFI) but suggested that AIC might be useful for comparing alternative, even nonnested models because of its absolute, as opposed to relative, nature. In a second large-scale simulation, Hu and Bentler [7] confirmed this finding and also found that AIC was the *least* sensitive to model misspecification error among the GFIs studied. In a thorough analysis of several SEM GFIs, McDonald and Marsh [10] explain how AIC tends to favor sparsely parameterized models in small samples and models that contain large numbers of free parameters (in the limit, saturated models) in large samples. Thus, despite its firm theoretical foundation and strong intuitive appeal, AIC has little empirical support to justify its application in practice. We agree with Hu and Bentler [7]: ‘We do not recommend [its] use’ (p. 446).

Allelic Association

Allelic association describes perhaps the simplest relationship between genes and phenotypes – differences in trait scores or disease frequencies with differences in alternative forms of a gene. For example, consider a genetic mutation that converts the DNA base pair Thymine to a Guanine, denoted $T \rightarrow G$. If having the T causes an increase in, say birth weight, then birth weight and the T allele are said to be associated. This concept of many small genetic effects dates back to the initial demonstration that discrete (Mendelian) changes in inherited material could lead to continuously varying phenotypes [8]. It is the cornerstone of the discipline of biometrical genetics [1, 7, 13].

For continuously measured phenotypes such as blood pressure or body weight, allelic association typically means that average levels of the trait differ according to the different alleles. For discrete traits such as diabetes or stroke, allelic association refers to different allele frequencies in groups of individuals who have the disease relative to those who do not. The general principle is the same in both cases: correlations between allele frequencies and outcomes. The statistical tools used to conduct the tests of significance are often different however [6].

Although formally the term ‘allelic association’ refers only to a specific allele, it generally encompasses **genotype** effects as well. For example, a diallelic locus with alleles T and G will produce genotypes TT, TG, and GG. Presence or absence of the T allele may be associated with higher trait values, but the genotypes themselves may offer a more precise association pattern, as is the case with different models of gene action (dominant, recessive, additive, multiplicative, etc.). Statistical tests of association based on individual alleles involve fewer parameters than genotype-based tests and thus are often preferred, but in practice, consideration of single-alleles versus genotypes is not just an esoteric statistical issue: the phenotype/allele/genotype relationship may have important consequences for gene identification and characterization. For example, mutations in the NOD2 locus for inflammatory bowel disease confer about a threefold increase in risk when considered as alleles, but as much as a 30- to 40-fold increase when considered as genotypes [10, 14].

As with any statistical correlation, the adage ‘correlation does not imply causation’ is also applicable in the domain of allelic association. Associated alleles may indeed cause changes in phenotypes, but they need not do so. Situations in which the associated alleles do cause trait changes are referred to as ‘direct’ associations, while situations in which different, but correlated, alleles cause the phenotype are referred to as ‘indirect’ associations [5]. The difference between direct and indirect association is depicted in Figure 1, in which the causal/susceptibility allele is depicted as a star and alleles at a correlated locus as circles. The frequency of the causal allele is higher in individuals with high trait values than with low trait values (70% versus 50%), as is the frequency of the noncausal correlated allele (50% versus 30%). Armed with just these frequencies, it would not be possible to determine which of the two loci is causal versus which is indirectly associated with the phenotype via a primary correlation with the disease allele.

In Figure 1, the correlation between the noncausal and causal loci is independent of the phenotype. They are correlated only because they are located close together on a chromosome and they have been transmitted together in the population over generations. We would not need to measure any traits to observe the correlation between the two genetic markers; it exists simply because of the history of the population studied. This correlation between alleles at different loci in a population is referred to as *linkage disequilibrium* (LD). Although the terms ‘linkage disequilibrium’ and ‘allelic association’ are sometimes used interchangeably in the literature, it is convenient and more precise to consider them as related but non-identical concepts. In general, the former refers to correlations between any two genetic loci, irrespective of disease, while the latter refers to a correlation between a genetic locus and a measured phenotype. This semantic distinction is important because LD and allelic association comprise different components of various disease-gene identification strategies. The widely used candidate-gene design involves a prior hypothesis about the role of some specific gene with a disease, and then evaluates genetic variants in that gene to test the correlation hypothesis [2]. These are thus the direct studies of allelic association. In contrast, the increasingly popular approaches involving hypothesis-free assessment of many loci scattered about large regions or the entire genome (positional

Figure 1 Example of indirect and direct association. The disease allele is shown as a filled star. Alleles at an anonymous marker are shown as circles. The two markers are correlated (in 'linkage disequilibrium') with one another. The frequency of the disease allele is greater in the individuals with high trait scores ($7/10 = 0.70$) versus those with low trait scores (0.50). Similarly, the correlated allele has higher frequency in high-trait individuals (0.50) versus low-trait individuals (0.30). Although the markers are correlated, they are not perfectly correlated, so it is difficult to distinguish the directly associated disease allele from the indirectly associated marker allele

cloning, candidate region, or whole-genome association designs) are indirect association strategies that rely on linkage disequilibrium between measured genetic markers and unmeasured causal loci [15].

From a sampling perspective, most association studies can be classified into two general groupings: case/control and family based. Historically, **case-control studies** have been used most widely, involving collections of sample of individuals who have a disease or trait of interest plus a sample of control individuals who do not have the trait (or who are randomly ascertained in some designs). Tests of allelic association involve comparisons of allele or genotype frequencies between the two groups. Matching between the case and control samples is a critical feature of this design, since differences between the

groups can be incorrectly ascribed to allelic association when in fact they reflect some unmeasured variable(s). Such spurious association outcomes are described as resulting from 'population stratification', or classical confounding in epidemiological terms.

Spurious association due to population stratification has worried geneticists considerably over the past two decades because human populations are known to have widely varying allele frequencies simply because of their different population histories [4]. Thus, one might expect many allele frequency differences between groups by chance alone. To address this concern, a number of family-based designs have been developed, popularized most widely in the Transmission Disequilibrium Test [17]. In this design, samples of affected offspring and their

two parents are collected (the disease status of the parents is usually irrelevant), and the frequencies of the alleles that are transmitted from parent to offspring form the 'case' group, while those that are present in the parents but not transmitted to the offspring form the 'control' group. The general idea is that drawing cases and controls from the same families renders the confounding allele frequency differences irrelevant. Similar strategies have been developed for continuous traits [9, 11, 12].

With the advent of family-based studies and with rapidly advancing studies of linkage disequilibrium across the human genome, the related concepts of linkage and association are becoming increasingly confused. The main distinction is that genetic linkage exists within families, while association extends to populations. More specifically, linkage refers to cosegregation of marker alleles with trait alleles within a family. Using the T $\rightarrow$ G example, a family would show evidence for linkage if members having high trait scores shared the T allele more often than expected by chance. However, another family would also show linkage if its members shared the G allele more often than expected by chance. In each case, an allele occurs in excess of expectations under random segregation, so each family is linked. In contrast, allelic association requires allelic overrepresentation across families. Thus, only if both families shared the same T (or G) allele would they offer joint evidence for association. In a simple sense, genetic linkage is allelic association within each family. The linkage-association distinction is important because linkage is useful for identifying large chromosome regions that harbor trait loci, but poor at identifying specific genetic variants, while association is more powerful in very tight regions but weak in identifying broad chromosomal locations. In addition, association analysis is more powerful than linkage for detecting alleles that are common in the population [16], whereas family-based linkage approaches offer the best available genetic approach to detect effects of rare alleles.

Association studies have not yielded many successes in detecting novel genes in the past, despite tens of thousands of attempts [18]. There are many postulated reasons for this lack of success, of which some of the most prominent are small sample sizes and poorly matched cases and controls [3]. In addition, there have been few large-effect complex trait

loci identified by any strategy, lending at least partial support to the traditional poly-/oligo-genic model, which posits that common trait variation results from many genes having individually small effects. To the extent that this model applies for a specific trait, so that each associated variant has an individually small effect on the trait, the sample size issue becomes even more problematic. Future studies are being designed to detect smaller effect sizes, which should help reveal the ultimate utility of the association approach for common traits.

All-X Models

All-X models are measurement models tested using **structural equation modeling** techniques in which all **latent variables** are treated as exogenous. The term ‘All-X’ is used because the letter X is conventionally used to represent measures of exogenous latent factors. As an example, consider a model in which two endogenous variables (η_1 and η_2), each measured with three items, are predicted from two exogenous variables (ξ_1 and ξ_2), each also measured with three items. Figure 1 provides a graphical representation of this model.

In this figure, x1 through x6 and y1 through y6 are scale items, λ_{11} through λ_{62} represent the loadings of each item on its respective factor, δ_1 through δ_6 and ε_1 through ε_6 are the measurement errors associated with each item, Φ_{12} is the correlation/covariance between the underlying exogenous latent variables, ψ_{12} is the correlation/covariance between the residuals of endogenous latent variables, β_{12} is the correlation/covariance between the underlying endogenous latent variables, and γ_{11} and γ_{22} are the relationships between the exogenous and endogenous latent variables.

This full model includes both structural and measurement relationships. Eight unique matrices are

Table 1 Eight unique matrices required to assess all elements of the model shown in Figure 1

<i>Lambda y</i>	= factor loadings of measured variables on the latent dependent variable
<i>Lambda x</i>	= factor loadings of measured variables on the latent independent variables
<i>Beta</i>	= interrelationships among ‘endogenous’ latent variables
<i>Gamma</i>	= relationships between ‘exogenous’ and ‘endogenous’ variables
<i>Phi</i>	= relationships among the exogenous variables
<i>Psi</i>	= relationships between residuals of the endogenous variables
<i>Theta delta</i>	= uniquenesses associated with indicators of exogenous variables
<i>Theta epsilon</i>	= uniquenesses associated with indicators of endogenous variables

required to fully assess all elements of this model. These matrices are shown in Table 1.

The left-hand panel of Figure 1 illustrates the relationships tested in an all-X measurement model.

Specifically, the first three items (x1–x3) are indicators of the first dimension and the second three items (x4–x6) are indicators of the second dimension. Model specification requires estimation of three sets of parameters including (a) loadings of measured variables on the underlying exogenous construct(s),

Figure 1 Model in which two endogenous variables (η_1 and η_2), each measured with three items, are predicted from two exogenous variables (ξ_1 and ξ_2), each also measured with three items

2 All-X Models

(b) measurement errors associated with the observed variables, and (c) relationships, if any, between the exogenous constructs.

Testing the all-X model requires the use of only three of the previously described eight matrices. The factor loadings would be contained in the lambda-x (λ_x) matrix, the measurement errors would be contained in the theta-delta (Θ_δ) matrix, and the

relationship between the factors would be captured in the phi (Φ) matrix.

© John Wiley & Sons, Ltd, Chichester, 2005

All-Y Models

All-Y models are measurement models tested using confirmatory factor analysis (*see* **Factor Analysis: Confirmatory**) in which all variables are treated as endogenous. For example, consider the situation described and illustrated under the ‘**all-X models**’ entry. The all-Y measurement model is captured in the right-hand panel of this figure. The first three items (y1 through y3) are indicators of the first latent endogenous variable (η_1), and the second three items (y4 through y6) are indicators of the second latent endogenous variable (η_2). Model specification requires estimation of three sets of parameters including (1) loadings of measured variables on the underlying construct(s), (2) relationships among measurement errors associated with the observed variables, and (3) relationships between the residual errors for the latent endogenous constructs.

Testing the all-Y model requires the use of only three of the eight matrices described in the ‘all-X’ entry. The factor loadings would be contained in the lambda-y (λ_y) matrix, the measurement error variances would be contained in the theta-epsilon (Θ_ϵ) matrix, and the relationships among the residual errors for the latent endogenous constructs would be captured in the psi (ψ) matrix.

All-Y models are similar to all-X models, with the important difference being the treatment of **latent variables** as endogenous, as opposed to exogenous. This difference requires the estimation of relationships between the residuals of the latent endogenous variables rather than the estimations of relationships among exogenous latents in all-X models.

Alternating Treatment Designs

Overview

The alternating treatments design (ATD) is a type of single-participant design (*see* **Single-Case Designs**) characterized by rapid and random/semirandom shifts between two or more conditions [1]. Essentially, conditions are alternated as often as necessary to capture meaningful measurement of the behavior of interest. For example, if daily measurement is the most telling way to measure the behavior of interest, conditions are alternated daily. Similarly, depending on the behavior of interest, conditions could be alternated bi-daily, weekly, by session, or by any other schedule that is appropriate for the behavior. In addition to the frequency with which conditions are changed, the order by which conditions are changed is a significant component of the ATD. Usually, conditions in an ATD are shifted semirandomly. The alternations are semirandom, rather than random, because there are restrictions on the number of times conditions can be sequentially implemented. Overall, the ATD is most commonly used to compare two or more treatments through the examination of treatment divergence and overlap [3]. Other uses include comparing a treatment to no treatment or inspecting treatment components.

To illustrate the use of the ATD in a classroom setting, consider a recent study by Skinner, Hurst, Teeple, and Meadows [5]. In this study, the researchers examined the effects of different mathematics assignments (control and experimental) on the on-task behavior and the rate of problem completion in students with emotional disturbance. The experimental assignment was similar to the control assignment with the addition of brief mathematics problems interspersed after every third problem. In a self-contained classroom, the researchers observed four students across 14 days (one 15-minute session per day) as the students completed the mathematics assignments. The assignment (control or experimental) was randomly selected on days 1, 5, 9, and 13. Then, the assignments were alternated daily so that if the students completed the experimental assignment on day 1, they would complete the control assignment

on day 2, and so on. Results suggested that the interspersal procedure produced an increase in problem completion and in on-task behavior.

Considerations

This research example illustrates certain considerations of using an ATD [3]. In particular, when using an ATD, questions regarding the number of conditions, baseline data, alternations, and analyses emerge. First, with regard to the number of conditions, it is important to understand that as the number of conditions increases, the complexity of the ATD increases in terms of drawing comparisons among conditions of the design. Consequently, it is generally recommended that the number of conditions not exceed three, and that each condition has at least two data points (although four or more are preferable). In the example, the researchers used two conditions, each with seven data points.

In terms of baseline data, a unique feature of the ATD, in comparison to other single-participant designs, is that baseline data are not required when one wants to examine the relative effectiveness of treatments that are already known to be effective (baseline data are usually required when a treatment's effectiveness has not been demonstrated). For example, because in the mathematics assignments Skinner et al. [5] used treatments that were already known to be effective, baseline data were not required. However, regardless of the known effectiveness, including baseline data before the ATD and as a condition within the ATD can provide useful information about individual change and the effectiveness of the treatments, while ruling out extraneous variables as the cause of change.

In addition to the number of conditions and baseline data, alternations are also aspects of the ATD that must be considered. First, as the number of alternations increase, the number of opportunities for divergence and overlap also increase. Because comparisons are made after examining divergence and overlap of conditions, increasing the number of alternations can yield more accurate results in the analyses. In general, although the number of alternations cannot be less than two, the maximum number of alternations varies depending on the study because the unit of measurement (e.g., day, week, session) and the duration of the treatment effect

2 Alternating Treatment Designs

influence the number of alternations. The variables in the example allowed for seven alternations.

Related to the number of alternations, but with more serious ramifications, is the way that conditions are alternated (e.g., order and schedule). The manner in which the conditions are alternated is important because it can threaten the validity of the ATD. In particular, the validity of the ATD can be threatened by sequential confounding, **carryover effects**, and alternation effects – a type of carryover effect [1]. Fortunately, although these concerns have the potential of threatening the validity of the ATD, they can usually be addressed by random or semi-random alternations and by monitoring for carryover effects. In addition to implementing a randomization strategy, the researchers in the example reported that naturally occurring absences also contributed to controlling for carryover effects.

A final consideration of using an ATD is the data analysis. Analysis of data in an ATD is important so that one can understand the effects of the treatment(s). As with other single-participant designs, data points in an ATD can be analyzed by visual inspection – that is, by assessing the level, trend, and variability within each condition [3]. This is the methodology used in the example [5] and is the most common way of analyzing data in single-participant designs. In addition to visual inspection, however, data from ATDs can also be analyzed with inferential statistics such as **randomization tests** [4]. Using this type of inferential analysis is unique to the ATD and can be accomplished by using available software packages [4] or doing hand calculations. It should be noted, however, that randomization tests are appropriate when alternations are truly random. Additional nonparametric tests that can be used to analyze data from an ATD include Wilcoxon's matched-pairs, signed-ranks tests (see **Paired Observations, Distribution Free Methods**), **sign tests**, and Friedman's analysis of variance (see **Friedman's Test**) [2].

Overall, depending on one's needs, the ATD is a useful design and presents certain advantages over other single-participant designs [3]. One advantage is that the ATD does not require the withdrawal of a treatment. This aspect of the ATD can be useful in avoiding or minimizing the ethical and practical issues that withdrawal of treatment can present. Another advantage of the ATD is that comparisons between treatments can be made more quickly than in other single-participant designs – sometimes in as little time as one session. A final advantage of the ATD, as discussed previously, is that the ATD does not require baseline data.

Analysis of Covariance

The control of nuisance variation is important in the design, analysis, and interpretation of experiments, quasi-experiments, and observational studies. The analysis of covariance (ANCOVA) is a method for controlling nuisance variation statistically. It can be used in place of, or in addition to, other approaches such as blocking (*see* **Block Random Assignment**) and **matching**. A variable that is of little experimental interest (such as verbal aptitude), but is believed to affect the response on the dependent variable (e.g., sales performance), is a **nuisance variable**. A measure of such a variable is called a covariate in the context of ANCOVA; it should be measured before treatments are applied.

There are two potential advantages of applying ANCOVA rather than a conventional **analysis of variance (ANOVA)** to data from a traditional randomized-groups design. First, the dependent variable means are adjusted to remove the variation that is predictable from chance differences on the covariate. Second, the ANCOVA error mean square is usually smaller than the corresponding ANOVA error mean square; this leads to narrower **confidence intervals**, increased **power**, and larger **effect size estimates**. The extent to which the means are adjusted and the error term is decreased depends upon several issues, the most important of which are the research design and the degree of relationship between the covariate and the dependent variable.

Design Issues

Because the randomized-groups design (*see* **Analysis of Variance: Classification**) yields groups that are probabilistically equivalent on all variables before treatments are applied, differences between covariate means are generally small (unless very small samples are used) and little adjustment of means is likely. But, if a useful covariate is employed, the size of the error mean square associated with the ANCOVA F test will be much smaller than the corresponding term in ANOVA. Hence, the major advantage of ANCOVA in a randomized-groups design is the reduction in the size of the error term.

When ANCOVA is applied to the biased assignment **quasi-experimental design** (often called the

regression-discontinuity design [4, 8]) where treatment groups are formed exclusively on the basis of the covariate score, the adjustment of the means will be large. This is a situation in which neither the unadjusted means nor the corresponding ANOVA F test supplies meaningful information about treatment effects. In contrast, the adjusted means and the corresponding ANCOVA F test supply relevant information about treatment effects.

Observational studies are also sometimes analyzed using ANCOVA. Although the covariate(s) often provides a major reduction in bias associated with group differences on confounding variables, it does not usually remove all such bias. Bias is likely to remain for at least two reasons. The first is measurement error in the covariate(s) and the second is omission of important (but often unknown) covariates in the model. Hence, ANCOVA results based on observational studies should be considered to have lower **Internal Validity** than results based on randomized experiments and quasi-experiments.

Nature of the Covariate

A covariate (X) is considered to be useful if it has a reasonably high correlation with the dependent variable (Y). It is typical for X and Y to be measures of different constructs (such as age and job performance), but in the application of ANCOVA to the randomized-groups pretest–posttest design, the pretest is used as the covariate and the posttest is used as the dependent variable. Because this pre–post design uses the same metric for both pre- and posttesting, several analytic approaches have been recommended. This design is ideal for illustrating the advantages of ANCOVA relative to other popular analysis methods.

Example

Consider the data from a randomized-groups pretest–posttest design presented in Table 1.

The purpose of the study is to evaluate three methods of training; the pretest is a measure of achievement obtained before training and the posttest is the measure of achievement obtained after training. Four methods of analyzing these data are described here. The first one, a one-factor ANOVA on posttest scores, is the least satisfactory because it ignores potentially

2 Analysis of Covariance

Table 1 Four analyses applied to a pretest–posttest randomized-groups experiment (taken from [4])

Treatment	Pretest (X)	Posttest (Y)	Difference ($Y - X$)

useful information contained in the pretest. It is included here to demonstrate the relative advantages of the other methods, all of which use the pretest information in some way.

The second approach is a one-factor ANOVA on the differences between the pretest and the posttest scores, often referred to as an analysis of change scores. The third approach is to treat the data as a two-factor split-plot factorial design (*see Analysis of Variance: Classification*) in which the three groups constitute the levels of the between-subjects factor and the two testing times (i.e., pre and post) constitute the levels of the repeated measurement factor. The last approach is a one-factor ANCOVA in which the pretest is used as the covariate and the posttest is used as the dependent variable.

The results of all four analytic approaches are summarized in Table 1. The group means based on variables X , Y , and $Y - X$ differences are shown, along with the adjusted Y means. Below the means are the summary tables for the four inferential analyses used to test for treatment effects. Before inspecting the P values associated with these analyses, notice the means on X . Even though random assignment was employed in forming the three small groups, it can be seen that there are annoying differences among these means. These group differences on the covariate may seem to cloud the interpretation of the differences among the means on Y . It is natural to wonder if the observed differences on the outcome are simply reflections of chance differences that were present among these groups at pretesting. This issue seems especially salient when the rank order of the Y means is the same as the rank order of the X means. Consequently, we are likely to lament the fact that random assignment has produced groups with different covariate means and to ponder the following question: ‘If the pretest (covariate) means had been exactly equivalent for all three groups, what are the predicted values of the posttest means?’ ANCOVA provides an answer to this question in the form of adjusted means. The direction of the adjustment follows the logic that a group starting with an advantage (i.e., a high $\bar{X}$) should have a downward adjustment to $\bar{Y}$, whereas a group starting with a disadvantage (i.e., a low $\bar{X}$) should have an upward adjustment to $\bar{Y}$.

Now consider the inferential results presented below the means in the table; it can be seen that the conclusions of the different analyses vary greatly.

The P values for the ANOVA on the posttest scores and the ANOVA on the difference scores are .47 and .19 respectively. The split-plot analysis provides three tests: a main-effects test for each factor and a test on the interaction. Only the interaction test is directly relevant to the question of whether there are differential effects of the treatments. The other tests can be ignored. The interaction test turns out to be just another, more cumbersome, way of evaluating whether we have sufficient evidence to claim that the difference-score means are the same for the three treatment groups. Hence, the null hypothesis of no interaction in the split-plot ANOVA is equivalent to the null hypothesis of equality of means in the one-factor ANOVA on difference scores.

Although these approaches are generally far more satisfactory than is a one-factor ANOVA on the posttest, the most satisfactory method is usually a one-factor ANCOVA on the posttest using the pretest as the covariate. Notice that the P value for ANCOVA ($p = .04$) is much smaller than those found using the other methods; it is the only one that leads to the conclusion that there is sufficient information to claim a treatment effect.

The main reason ANOVA on difference scores is usually less satisfactory than ANCOVA is that the latter typically has a smaller error mean square. This occurs because ANOVA on difference scores implicitly assumes that the value of the population within group regression slope is 1.0 (whether it actually is or not), whereas in the case of ANCOVA, the within group slope is estimated from the data. This difference is important because the error variation in both analyses refers to deviations from the within group slope. If the actual slope is far from 1.0, the ANCOVA error mean square will be much smaller than the error mean square associated with the ANOVA on $Y - X$ differences. The example data illustrate this point. The estimated within group slope is 2.2 and the associated ANCOVA error mean square is less than one-half the size of the ANOVA error mean square.

In summary, this example shows that information on the pretest can be used either as a covariate or to form pretest–posttest differences, but it is more effective to use it as a covariate. Although there are conditions in which this will not be true, ANCOVA is usually the preferred analysis of the randomized-groups pretest–posttest design. By the way, no additional

advantage is obtained by combining both approaches in a single analysis. If we carry out ANCOVA using the pretest as the covariate and the difference scores rather than the posttest scores as the dependent variable, the error mean square and the P value from this analysis will be identical to those shown in Table 1.

Assumptions

Several assumptions in addition to those normally associated with ANOVA (viz., homogeneity of population variances, normality of population error distributions, and independence of errors) are associated with the ANCOVA model. Among the most important are the assumptions that the relationship between the covariate and the dependent variable is linear, that the covariate is measured without error, that the within group regression slopes are homogeneous, and that the treatments do not affect the covariate.

Alternatives and Extensions

A simple alternative to a one-factor ANCOVA is to use a two-factor (treatments by blocks) ANOVA in which block levels are formed using scores on X (see **Randomized Block Designs**). Although this approach has the advantage of not requiring a linear relationship between X and Y , it also has several disadvantages including the reduction of error degrees of freedom and the censoring of information on X . Comparisons of the two approaches usually reveal higher power for ANCOVA, especially if the treatment groups can be formed using restricted randomization rather than simple random assignment.

Alternatives to conventional ANCOVA are now available to accommodate violations of any of the assumptions listed above [4]. Some of these alternatives require minor modifications of conventional ANCOVA computational procedures. Others such as those designed for dichotomously scaled dependent variables, robust analysis [3], complex matching [7], random treatment effects [6], and intragroup dependency of errors [6] require specialized software. Straightforward extensions of covariance analysis are available for experimental designs having more than one factor (multiple-factor ANCOVA), more than one dependent variable (multivariate ANCOVA), and more than one covariate (multiple ANCOVA). Most of these extensions are described in standard references on experimental design [1, 2, 5].

Analysis of Covariance: Nonparametric

Many studies are designed to clarify the relationship between two variables, a predictor (often an exposure in epidemiological study or a treatment in a medical trial) and an outcome. Yet, in almost all of these studies there is a third type of variable measured, a covariate. A covariate may be a confounder if it is both predictive of the outcome and associated with the predictor. For example, a simple comparison of survival times (an outcome) between cancer patients and subjects receiving a flu vaccine (so the predictor is binary, cancer vs. at risk for influenza) would likely demonstrate better survival for the subjects than for the patients. An uncritical interpretation of this finding might then be that the flu vaccine is superior to cancer treatment at extending survival, and so even cancer patients should have the flu vaccine (in lieu of their usual cancer treatment).

The problem with this interpretation, aside from its obvious conflict with intuition, is that it ignores the confounder, disease severity. The patients tend to have more severe disease than the subjects, so disease severity is associated with the predictor. In addition, those with less severe disease will tend to live longer, regardless of how they are treated, than those with a more severe disease, and so disease severity is also associated with the outcome. It might be of greater interest, then, to adjust or control for disease severity when making the survival comparison. Intuitively, one would wish to make the survival comparisons across treatment groups within levels of disease severity, so that apples are compared with apples and oranges are compared with oranges. More formally, a ‘covariate cannot be responsible for confounding within a stratum that is internally homogeneous with respect to the covariate’ [10]. Koch et al. [11] make explicit five benefits in adjusting an analysis for one or several covariates, including:

1. bias reduction through adjustment for baseline imbalances in covariate distributions (especially in observational studies);
2. better power through variance reduction;
3. creating comparable comparison groups;
4. clarifying the predictive ability of one or several covariates;

5. clarifying the uniformity of treatment effects over subpopulations defined by particular values or ranges of covariates.

In a subsequent article [12], some of the same authors (and others) stated that the first benefit does not apply to randomized trials (*see Randomization*) because ‘randomization provides statistically equivalent groups at baseline (that is, any departures from equivalence are random)’. Yet, systematic baseline imbalances (selection bias) can, in fact, occur even in properly randomized trials [5, 6], and so even the first benefit applies to randomized trials.

The fewer assumptions required, the better. Unfortunately, the validity of the popular **analysis of covariance** (ANCOVA) model is predicated on a variety of assumptions including normality of residuals, equal variances, linearity, and independence. When these assumptions are not met, the ANCOVA may not be robust [13]. By not requiring such assumptions, a nonparametric analysis offers better robustness properties. In Table 11 (pp. 590, 591) of [11] are listed numerous covariance techniques for categorical data, along with the assumptions required by each. Generally, even methods that are considered nonparametric, such as those discussed in [1] and [19], rely on the **central limit theorem**, chi-squared distributional assumptions for quadratic forms, and/or link functions connecting covariates to outcomes. The ideal situation is when no assumptions are required and inference can proceed on the basis of randomization (which is known, and hence is not an assumption).

In a randomized trial, exact design-based analyses are permutation tests (*see Permutation Based Inference; Linear Models: Permutation Methods*) [2, 7], which tend to be conducted without adjusting for covariates. In fact, there are several ways to build covariate adjustment into a permutation test. We note that while a continuous variable may be seen as an extension of a categorical variable (each outcome constitutes its own category), there is a qualitative difference in the way adjustment is conducted for continuous covariates. Specifically, adjustment for an ordinal covariate tends to be conducted by comparing treatment groups only within values of the covariate; there is no attempt to make comparisons across covariate values. In contrast, models tend to be fit when adjusting for continuous covariates, thereby allowing such disparate comparisons to be made.

2 Analysis of Covariance: Nonparametric

We will consider only categorical covariates, but distinguish nominal (including binary) covariates from ordinal covariates.

Koch et al. [11] present a data set with 59 patients, two treatment groups (active and placebo), five response status levels (excellent, good, moderate, fair, poor), and age as a continuous covariate. In their Table 5 (p. 577), the response variable is dichotomized into good and excellent versus moderate, fair, or poor. We then dichotomize the age into 54 or less (younger) versus 55 or over (older). Dichotomizing an ordinal response variable can result in a loss of **power** [3, 14, 16], and dichotomizing an ordinal covariate can result in a reversal of the direction of the effect [9], but we do so for the sake of simplicity. The data structure is then a $2 \times 2 \times 2$ table:

Now if the randomization was unrestricted other than the restriction that 32 patients were to receive placebo and 27 were to receive the active treatment, there would be $59!/([32!27!])$ ways to select 32 patients out of 59 to constitute the placebo group. An unadjusted permutation test would compare the test statistic of the observed table to the reference distribution consisting of the test statistics computed under the null hypothesis [2, 7] of all permuted tables (possible realizations of the randomization). To adjust for age, one can use an adjusted test statistic that combines age-specific measures of the treatment effect. This could be done with an essentially unrestricted (other than the requirement that the row margins be fixed) permutation test.

It is also possible to adjust for age by using an unadjusted test statistic (a simple difference across treatment groups in response rates) with a restricted permutation sample space (only those tables that retain the age*treatment distribution). One could also use both the adjusted test statistic and the adjusted permutation sample space. We find that for that data set in Table 1, the unadjusted difference in proportions (active minus placebo) is 0.4051, whereas the

weighted average of age-specific differences in proportions is 0.3254. That is, the differences in proportions are computed within each age group (young and old), and these differences are weighted by the relative frequencies of each age group, to obtain 0.3254. Monte Carlo (*see Monte Carlo Simulation*) P values based on resampling from the permutation distribution with 25 000 permutations yields a P value of 0.0017 unadjusted. This is the proportion of permutations with unadjusted test statistics at least as large as 0.4051. The proportion with adjusted test statistics at least as large as 0.3254 is 0.0036, so this is the first adjusted P value.

Next, consider only the restricted set of permutations that retain the age imbalance across treatment groups, that is, permutations in which 17 younger and 15 older cases are assigned to the placebo and 7 younger and 20 older cases are assigned to the active treatment. The number of permissible permutations can be expressed as the product of the number of ways of assigning the younger cases, $24!/([17!7!])$, and the number of ways of assigning the older cases, $35!/([15!20!])$. The proportion of Monte Carlo permutations with unadjusted test statistics at least as large as 0.4051 is 0.0086, so this is the second adjusted P value. Considering only the restricted set of permutations that retain the age imbalance across treatment groups, the proportion of permutations with adjusted test statistics at least as large as 0.3254 is 0.0082, so this is the third adjusted P value, or the doubly adjusted P value [4]. Of course, the set of numerical values of the various P values for a given set of data does not serve as a basis for selecting one adjustment technique or another. Rather, this decision should be based on the relative importance of testing and estimation, because obtaining a valid P value by comparing a distorted estimate to other equally distorted estimates does not help with valid estimation. The double adjustment technique might be ideal for ensuring both valid testing and valid estimation [4].

Table 1 A simplified $2 \times 2 \times 2$ contingency table. (Reproduced from Koch, G.G., Amara, I.A., Davis, G.W. & Gillings, D.B. (1982). A review of some statistical methods for covariance analysis of categorical data, *Biometrics* **38**, 563–595 [11])

	Younger		Older		Total
	Unfavorable	Favorable	Unfavorable	Favorable	
Placebo	15	2	11	4	32
Active	5	2	6	14	27
Total	20	4	17	18	59

Another exact permutation adjustment technique applies to ordered categorical covariates measured on the same scale as the ordered categorical response variable [8]. The idea here is to consider the information-preserving composite end point [3], which consists of the combination of the baseline value (the covariate) and the subsequent outcome measure. Instead of assigning arbitrary numerical scores and then considering a difference from baseline (as is frequently done in practice), this approach is based on a partial ordering on the set of possible values for the pair (baseline, final outcome), and then a U test.

Regardless of the scale on which the covariate is measured, it needs to be a true covariate, meaning that it is not influenced by the treatments, because adjustment for variables measured subsequent to randomization is known to lead to unreliable results [17, 18]. Covariates measured after randomization have been called *pseudocovariates* [15], and the subgroups defined by them have been called *improper subgroups* [20].

Analysis of Variance

Statistical tests have been employed since the early eighteenth century, and the basic model that underlies much of modern statistics has been explored since its formulation by Legendre and **Gauss** in the early nineteenth century. Yet, it was not until the early twentieth century, when **R. A. Fisher** introduced the analysis of variance [2–4, 7], that a systematic method based on exact sampling distributions was put into place. The method allowed for inferences to be drawn from sample statistics to population characteristics of interest. The analysis of variance united methods that were previously only approximate, were developed separately, and were seemingly unrelated, into one exact procedure whose results could be reported in a single compact table.

In the inferential procedure explicated by Fisher, the actual data in an experiment are considered to be a random sample from a hypothetical infinite population that was assumed to be appropriately modeled by distributions specified by relatively few parameters [2]. For instance, in terms of a particular observable measure, the population could consist of data that follow a normal distribution. The parameters of this distribution are the mean and variance (it was Fisher who introduced the word ‘variance’ to denote the square of the standard deviation). Or, alternatively, four normally distributed populations could have been sampled, possibly having different means and variances. The question then naturally arises as to whether corresponding characteristics of the populations are equal.

In order to investigate this matter, we formulate what Fisher called a null hypothesis, usually denoted by H_0 . This hypothesis specifies a function of the parameters related to the question of interest. In the present case, we might specify the hypothesis in terms of the population means μ_k

$$H_0: \mu_1 = \mu_2 = \cdots = \mu_K, \quad (1)$$

where K is the number of populations whose means we are comparing. According to Fisher [6], the term ‘null hypothesis’ was chosen by analogy with a device used to measure electrical resistance. In this device, an indicator dial showing no deflection indicated that the correct value was determined. In the same way, if the null hypothesis is true, then any

discrepancies of the sample means from one another are due to the errors of random sampling.

Fisher at one time revealingly referred to the analysis of variance as the analysis of variation [7]. The analysis consists of partitioning the overall variability present in the data into parts reflecting the variability accounted for by explanatory factors and the variability due to chance. These different sources of variability are measured by particular sums of squared deviations. For instance, the total variability to be studied is equal to the sum of the squares of the differences between the observations and the overall sample mean. If the amount of variability accounted for by the explanatory factor was sufficiently larger than the magnitude we would expect simply because of the vagaries of random sampling, we would conclude that there was a nonzero effect in the population due to the factor under examination [7].

The basic partition of the total variability utilizes the algebraic identity

$$\begin{aligned} \sum_{i=1}^N (Y_{ik} - \bar{Y})^2 &= \sum_{k=1}^K N_k (\bar{Y}_k - \bar{Y})^2 \\ &\quad + \sum_{k=1}^K \sum_{i=1}^{N_k} (Y_{ik} - \bar{Y}_k)^2, \end{aligned} \quad (2)$$

or

$$SST = SSB + SSW. \quad (3)$$

SST is the sum of squares total and refers to the overall sum of squared deviations of the observations about the combined group mean $\bar{Y}$. SSB is the sum of squares between groups and refers to the variability of the individual group means $\bar{Y}_k$ about the combined group mean. SSW is the sum of squares within groups and refers to the variability of the observations about their separate group means. The sum of squares between groups is that part of the total variability that reflects possible differences among the groups.

Let us also assume in the present case that the K population variances are equal. Then in sampling from K normal populations with equal variances and equal means under the null hypothesis, we are in effect sampling K samples from a single population. And if the null hypothesis is true, the variability among the sample means should be reflective of the known variance of means in repeated sampling from

2 Analysis of Variance

a single population. This variance is

$$\sigma_{\bar{Y}}^2 = \frac{\sigma^2}{N}, \quad (4)$$

where $\sigma_{\bar{Y}}^2$ is the variance of all possible sample means, σ^2 denotes the population variance, and N is the total sample size. With the sample estimate of a population variance given by

$$S^2 = \frac{\sum_{i=1}^N (Y_i - \bar{Y})^2}{(N - 1)},$$

$\sigma_{\bar{Y}}^2$ can be estimated in the sample by

$$S_{\bar{Y}}^2 = \frac{\sum_{k=1}^K (\bar{Y}_k - \bar{Y})^2}{(K - 1)}.$$

Finally, then,

$$\begin{aligned} NS_{\bar{Y}}^2 &= N \sum_{k=1}^K \frac{(\bar{Y}_k - \bar{Y})^2}{(K - 1)} = \frac{1}{(K - 1)} \\ &\times \sum_{k=1}^K N(\bar{Y}_k - \bar{Y})^2 = \frac{SSB}{(K - 1)} \end{aligned}$$

is an estimate of the population variance if the null hypothesis is true. The ratio of SSB to $(K - 1)$ is called the *mean square* between, MSB , where $(K - 1)$ is the number of degrees of freedom associated with this variance estimate.

If the null hypothesis is true, then MSB provides an unbiased estimate of the population variance. If the null hypothesis is false, however, MSB overestimates the population variance, because the sample means will vary about their own population means and will tend to lie further from the combined group mean than they would under H_0 . We can get an indication, then, of the possible falseness of the null hypothesis by comparing the MSB to an independent estimate of the population variance.

Fortunately, we have available a second estimate of the population variance, based on the K separate sample variances. Fisher [3] showed that the best way to combine these separate estimates into a single pooled estimator of the common population variance

is to divide the sum of squares within by $(N - K)$, resulting in the mean square within,

$$MSW = \frac{\sum_{k=1}^K \sum_{i=1}^{N_k} (Y_{ik} - \bar{Y}_k)^2}{(N - K)} = \frac{\sum_{k=1}^K (N_k - 1)S_k^2}{(N - K)},$$

based on $(N - K)$ degrees of freedom. Fisher showed that the mean square within is an unbiased estimate of the population variance, regardless of the truth of the null hypothesis. Finally, Fisher showed [1] that these two estimates are statistically independent of one another.

We have, then, two independent estimates of the common population variance, one of which, the mean square between, is unbiased only if the null hypothesis is true, otherwise tending to be too large. It is a remarkable feature of the analysis of variance that a test of the hypothesis concerning the equality of population means can be performed by testing the equality of two variances, σ^2 and $N\sigma_{\bar{Y}}^2$.

Fisher [4] first formulated an approximate test that both MSB and MSW estimate the same value by using the logarithm of the ratio MSB/MSW , which he labeled z . He did so for two reasons. First, the distribution of the logarithm of the sample variance approaches the normal distribution with increasing sample sizes, so he could use well-known procedures based on the normal distribution to perform the test involving the two variances. More importantly, the variability of a sample variance involves the population variance, which is unknown, whereas the variability of the logarithm of the sample variance only involves the sample size. Therefore, the unknown population variance would not enter a procedure based on the approximate distribution of z .

The population variance would need to be eliminated from the problem at hand in order for the test to be exact and not approximate. This is precisely what Fisher accomplished. Helmer had shown that for a normally distributed variable Y , with mean μ and variance σ^2 , $\sum_{i=1}^p (Y_i - \mu)^2 / \sigma^2$ follows a chi-square distribution with p degrees of freedom, denoted χ_p^2 . Pizzetti [9] showed that $\sum_{i=1}^p (Y_i - \bar{Y})^2 / \sigma^2$ follows a χ_{p-1}^2 distribution. Consider then the sum of squares between. Each of the sample means $\bar{Y}_k$ is normally distributed with variance $\sigma_{\bar{Y}}^2 = \sigma^2 / N_k$, the overall average of the sample means is $\bar{Y}$, and we have seen that under the

null hypothesis, the K samples are effectively drawn from the same population. Pizzetti's result tells us that

$$\sum_{k=1}^K \frac{(\bar{Y}_k - \bar{Y})^2}{\sigma^2/N_k} = \sum_{k=1}^K \frac{N_k(\bar{Y}_k - \bar{Y})^2}{\sigma^2} = \frac{SSB}{\sigma^2}$$

follows a χ_{K-1}^2 distribution, and so MSB/σ^2 has a distribution that is $1/(K-1)$ times a χ_{K-1}^2 distributed variable. Similarly, we find that MSW/σ^2 has a distribution that is $1/(N-K)$ times a χ_{N-K}^2 distributed variable. Finally, then, we see that the ratio

$$\frac{[MSB/\sigma^2]}{[MSW/\sigma^2]} = \frac{MSB}{MSW}$$

is distributed as the ratio of two independent chi-square distributed variables, each divided by its degrees of freedom. It is the distribution of this ratio that Fisher derived. **Snedecor** named the ratio F in Fisher's honor, reputedly [11] 'for which officiousness Fisher never seems to have forgiven him'.

The distribution of the F -ratio is actually a family of distributions. The particular distribution appropriate to the problem at hand is determined by two parameters, the number of degrees of freedom associated with the numerator and denominator estimates of the variance. As desired, the ratio of the two mean squares reflects the relative amounts of variability attributed to the explanatory factor of interest and to chance. The F distribution allows us to specify a cutoff, called a *critical value* (see **Critical Region**). F -ratios larger than the critical value lead us to conclude that [5] 'either there is something in the [mean differences], or a coincidence has occurred ...' A small percentage of the time, we can obtain a large F -ratio even when the null hypothesis is true, on the basis of which we would conclude incorrectly that H_0 is false. Fisher often set the rate at which we would commit this error, known as a Type I error, at 0.05 or 0.01; the corresponding critical values would be the 95th or 99th cumulative percentiles of the F distribution.

Neyman and **Pearson** [10] introduced the concept of an alternative hypothesis, denoted H_1 , which reflected the conclusion to be drawn regarding the population parameters if the null hypothesis were rejected. They also pointed to a second kind of error that could occur, the failure to reject a false null hypothesis, called a *Type II error*, with an

associated Type II error rate. The rate of correct rejection of H_0 is known as the power of the test. Fisher rarely acknowledged the contributions of the Neyman and Pearson method of hypothesis testing. He did, nevertheless, derive the non-null distribution of the F -ratio, which allowed the power of tests to be calculated.

As an example of an analysis of variance, consider the data reported in a study [8] of the effects of four treatments on posttraumatic stress disorder (PSD), summarized in Table 1. The dependent variable is a posttest measure of the severity of PSD. On the basis of pooling the sample variances, the MSW is found to equal 55.71. From the sample means and sample sizes, the combined group mean is calculated to be 15.62, and using these values and $K = 4$, the MSB is determined to equal 169.32. Finally, the F -ratio is found to be 3.04. These results are usually summarized in an analysis of variance table, shown in Table 2. From a table of the F distribution with numerator degrees of freedom equal to $K - 1 = 3$, denominator degrees of freedom equal to $N - K = 41$, and Type I error rate set to 0.05, we find the critical value is equal to 2.83. Because the observed F -ratio exceeds the critical value, we conclude that the test is significant and that the null hypothesis is false.

This example points to a difficulty associated with the analysis of a variance test, namely, that although

Table 1 Summary data from study of traumatic stress disorder

	Treatment group ^a			
	SIT	PE	SC	WL
N_k	14	10	11	10
$\bar{Y}_k$	11.07	15.40	18.09	19.50
S_k^2	15.76	122.99	50.84	51.55

Note: ^aSIT = stress inoculation therapy, PE = prolonged exposure, SC = supportive counseling, WL = wait-list control.

Total	44	2792.10		

we have concluded that the population means differ, we still do not know in what ways they differ. It seems likely that this more focused information would be particularly useful. One possible solution would involve testing the means for equality in a pairwise fashion, but this approach would engender its own problems. Most importantly, if each pairwise test were conducted with a Type I error rate of 0.05, then the rate at which we would falsely conclude that the means are not all equal could greatly exceed 0.05. Fisher introduced a method, known as a **multiple comparison procedure** for performing the desired pairwise comparisons, but it failed to hold the Type I error rate at the desired level in all circumstances. Many other multiple comparison procedures have since been developed that either bypass the F test or take advantage of its properties and successfully control the overall Type I error rate.

Analysis of Variance: Cell Means Approach

Analysis of variance, ANOVA, is typically introduced in textbooks by means of the classical ANOVA model. This model for a completely randomized design is

$$Y_{ij} = \mu + \alpha_j + \varepsilon_{i(j)} \quad (i = 1, \dots, n; j = 1, \dots, p), \quad (1)$$

where Y_{ij} is the observation for participant i in treatment level j , μ is the grand mean, α_j is the treatment effect for population j , and $\varepsilon_{i(j)}$ is the error effect that is i.i.d. $N(0, \sigma_\varepsilon^2)$. The focus of the model is on treatment effects, α_j 's. However, according to Urquhart, Weeks, and Henderson [9], **Ronald A. Fisher's** early development of ANOVA was conceptualized by his colleagues in terms of cell means, μ_j . It was not until later that a cell mean was given a linear structure in terms of the grand mean plus a treatment effect, that is, $\mu_j = \mu + \alpha_j$.

The cell means model is an alternative ANOVA model. This model for a **completely randomized design** is

$$Y_{ij} = \mu_j + \varepsilon_{i(j)} \quad (i = 1, \dots, n; j = 1, \dots, p), \quad (2)$$

where μ_j is the population mean for treatment level j and $\varepsilon_{i(j)}$ is the error effect that is i.i.d. $N(0, \sigma_\varepsilon^2)$. The cell means model replaces two parameters of the classical model, the grand mean and treatment effect, with one parameter, the cell mean. It seems that Fisher did not use either model (1) or (2). However, the cell means model is consistent with his early development of ANOVA as an analysis of differences among observed means [5, p. 12]. The advantages of the cell means model approach to the ANOVA are well documented [1–8, 10]. The advantages are most evident for multitreatment experiments with unequal cell n 's or empty cells (see **Missing Data**). Two versions of the cell means model are described: the unrestricted model and the restricted model. To simplify the presentation, a **fixed-effects model** will be assumed throughout the discussion.

Unrestricted Cell Means Model

The unrestricted model is illustrated using an experiment from Kirk [2, p. 166]. The experiment is concerned with the effects of sleep deprivation on hand steadiness. Because of space limitations, only a portion of the data is used. $N = 12$ participants were randomly assigned to $p = 3$ conditions of sleep deprivation, 12, 24, and 36 hours, with the restriction that $n = 4$ participants were assigned to each condition. The dependent variable was a measure of hand steadiness; large scores indicate lack of steadiness. The data are presented in Table 1. The null hypothesis for these data is $H_0: \mu_1 = \mu_2 = \mu_3$. Three equivalent null hypotheses that can be used with the cell means model are

$$\begin{aligned} H_0: \mu_1 - \mu_2 &= 0 & H_0: \mu_1 - \mu_3 &= 0 \\ \mu_2 - \mu_3 &= 0 & \mu_2 - \mu_3 &= 0 \\ H_0: \mu_1 - \mu_2 &= 0 \\ \mu_1 - \mu_3 &= 0. \end{aligned} \quad (3)$$

In matrix notation, the first null hypothesis is written as

$$\begin{array}{ccc} \text{Coefficient} & \text{Mean} & \text{Null} \\ \text{matrix} & \text{vector} & \text{vector} \\ \mathbf{C}' & \boldsymbol{\mu} & \mathbf{0} \\ \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} & \begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{bmatrix} & = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \end{array} \quad (4)$$

where $\mathbf{C}'$ is a $(p-1) \times p$ coefficient matrix of full row rank that defines the null hypothesis, $\boldsymbol{\mu}$ is a $p \times 1$ vector of population means, and $\mathbf{0}$ is a $(p-1) \times 1$ vector of zeros.

For a completely randomized ANOVA, the total sum of square, $SSTOTAL$, can be partitioned into the sum of squares between groups, $SSBG$, and the sum of squares within groups, $SSWG$. Formulas

Table 1 Hand unsteadiness data for three conditions of sleep deprivation

a_1	a_2	a_3
12 hours	24 hours	36 hours
2	3	5
1	5	7
6	4	6
3	4	10
$\bar{Y}_{ij} = 3$	4	7

2 Analysis of Variance: Cell Means Approach

for computing these sums of squares using vectors, matrices, and a scalar are

$$\begin{aligned} SSTOTAL &= \mathbf{y}'\mathbf{y} - \mathbf{y}'\mathbf{J}\mathbf{y}N^{-1} \\ SSBG &= (\mathbf{C}'\hat{\boldsymbol{\mu}} - \mathbf{0})'[\mathbf{C}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}]^{-1}(\mathbf{C}'\hat{\boldsymbol{\mu}} - \mathbf{0}) \\ SSWG &= \mathbf{y}'\mathbf{y} - \hat{\boldsymbol{\mu}}'\mathbf{X}'\mathbf{y}, \end{aligned} \quad (5)$$

where $\mathbf{y}$ is an $N \times 1$ vector of observations and $\mathbf{X}$ is an $N \times p$ structural matrix that indicates the treatment level in which an observation appears. The $\mathbf{X}$ matrix contains ones and zeros such that each row has only one one and each column has as many ones as there are observations from the corresponding population. For the data in Table 1, $\mathbf{y}$ and $\mathbf{X}$ are

$$\begin{array}{c} \mathbf{y} \\ \mathbf{X} \end{array} \begin{array}{c} \left\{ \begin{array}{c} a_1 \\ a_2 \\ a_3 \end{array} \right\} \begin{bmatrix} 2 \\ 1 \\ 6 \\ 3 \\ 3 \\ 5 \\ 4 \\ 4 \\ 5 \\ 7 \\ 6 \\ 10 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix} \end{array}$$

$\mathbf{J}$ is an $N \times N$ matrix of ones and is obtained from the product of an $N \times 1$ vector of ones, $\mathbf{1}$, (column sum vector) and a $1 \times N$ vector of ones, $\mathbf{1}'$ (row sum vector). $\hat{\boldsymbol{\mu}}$ is a $p \times 1$ vector of sample means and is given by

$$(\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{y} = \hat{\boldsymbol{\mu}} \quad (6)$$

$$\begin{bmatrix} \frac{1}{4} & 0 & 0 \\ 0 & \frac{1}{4} & 0 \\ 0 & 0 & \frac{1}{4} \end{bmatrix} \begin{bmatrix} 12 \\ 16 \\ 28 \end{bmatrix} = \begin{bmatrix} 3 \\ 4 \\ 7 \end{bmatrix}.$$

$(\mathbf{X}'\mathbf{X})^{-1}$ is a $p \times p$ diagonal matrix whose elements are the inverse of the sample n 's for each treatment level.

An advantage of the cell means model is that a representation, $\mathbf{C}'\hat{\boldsymbol{\mu}} - \mathbf{0}$, of the null hypothesis, $\mathbf{C}'\boldsymbol{\mu} = \mathbf{0}$, always appears in the formula for $SSBG$. Hence there is never any ambiguity about the hypothesis that this sum of squares is used to test. Because $\mathbf{0}$ in $\mathbf{C}'\hat{\boldsymbol{\mu}} - \mathbf{0}$ is a vector of zeros, the

formula for $SSBG$ simplifies to

$$SSBG = (\mathbf{C}'\hat{\boldsymbol{\mu}})'[\mathbf{C}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}]^{-1}(\mathbf{C}'\hat{\boldsymbol{\mu}}). \quad (7)$$

The between groups, within groups, and total sums of squares for the data in Table 1 are, respectively,

$$\begin{aligned} SSBG &= (\mathbf{C}'\hat{\boldsymbol{\mu}})'[\mathbf{C}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}]^{-1}(\mathbf{C}'\hat{\boldsymbol{\mu}}) \\ &= 34.6667 \\ SSWG &= \mathbf{y}'\mathbf{y} - \hat{\boldsymbol{\mu}}'\mathbf{X}'\mathbf{y} \\ &= 326.0000 - 296.0000 = 30.0000 \\ SSTOTAL &= \mathbf{y}'\mathbf{y} - \mathbf{y}'\mathbf{J}\mathbf{y}N^{-1} \\ &= 326.0000 - 261.3333 = 64.6667. \end{aligned} \quad (8)$$

The between and within groups mean square are given by

$$\begin{aligned} MSBG &= \frac{SSBG}{(p-1)} = \frac{34.6667}{2} = 17.3333 \\ MSWG &= \frac{SSWG}{[p(n-1)]} = \frac{30.0000}{[3(4-1)]} = 3.3333. \end{aligned} \quad (9)$$

The F statistic and P value are

$$F = \frac{MSBG}{MSWG} = \frac{17.3333}{3.3333} = 5.20, \quad P = .04. \quad (10)$$

The computation of the three sums of squares is easily performed with any computer package that performs matrix operations.

Restricted Cell Means Model

A second form of the cell means model enables a researcher to test a null hypothesis subject to one or more restrictions. This cell means model is called a restricted model. The restrictions represent assumptions about the means of the populations that are sampled. Consider a randomized block ANOVA design where it is assumed that the treatment and blocks do not interact. The restricted cell means model for this design is

$$Y_{ij} = \mu_{ij} + \varepsilon_{i(j)} \quad (i = 1, \dots, n; \quad j = 1, \dots, p), \quad (11)$$

where μ_{ij} is the population mean for block i and treatment level j , $\varepsilon_{i(j)}$ is the error effect that is i.i.d. $N(0, \sigma_\varepsilon^2)$, and μ_{ij} is subject to the restrictions that

$$\mu_{ij} - \mu_{i'j} - \mu_{ij'} + \mu_{i'j'} = 0 \text{ for all } i, i', j, \text{ and } j'. \quad (12)$$

The restrictions on μ_{ij} state that all block-treatment interaction effects equal zero. These restrictions, which are a part of the model, are imposed when the cell n_{ij} 's are equal to one as in a randomized block design and it is not possible to estimate error effects separately from interaction effects.

Consider a randomized block design with $p = 3$ treatment levels and $n = 4$ blocks. Only four blocks

$$\begin{array}{ccc} \text{Hypothesis} & \text{Mean} & \text{Null} \\ \text{matrix} & \text{vector} & \text{vector} \\ \mathbf{H}'_{BL} & \begin{bmatrix} \mu_{BL} \\ \mu_{1\cdot} \\ \mu_{2\cdot} \\ \mu_{3\cdot} \\ \mu_{4\cdot} \end{bmatrix} & \begin{bmatrix} \mathbf{0}_{BL} \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \end{array} \quad (14)$$

$$\begin{bmatrix} 1 & -1 & 0 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} \mu_{BL} \\ \mu_{1\cdot} \\ \mu_{2\cdot} \\ \mu_{3\cdot} \\ \mu_{4\cdot} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}.$$

The randomized block design has $np = h$ sample means. The $1 \times h$ vector of means is $\boldsymbol{\mu}' = [\hat{\mu}_{11} \hat{\mu}_{21} \hat{\mu}_{31} \hat{\mu}_{41} \hat{\mu}_{12} \hat{\mu}_{22}, \dots, \hat{\mu}_{43}]$. The coefficient matrices for computing sums of squares for treatment A , blocks, and the block-treatment interaction are denoted by $\mathbf{C}'_A$, $\mathbf{C}'_{BL}$, and $\mathbf{R}'$, respectively. These coefficient matrices are easily obtained from Kronecker products, $\otimes$, as follows:

$$\begin{aligned} & \mathbf{H}'_A \otimes \frac{1}{n} \mathbf{1}'_{BL} = \frac{1}{n} \begin{bmatrix} 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \end{bmatrix} \\ & \frac{1}{p} \mathbf{1}'_A \otimes \mathbf{H}'_{BL} = \frac{1}{p} \begin{bmatrix} 1 & -1 & 0 & 0 & 1 & -1 & 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & 1 & -1 & 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & 1 & -1 & 0 & 0 & 1 & -1 \end{bmatrix} \quad (15) \\ & \mathbf{H}'_A \otimes \mathbf{H}'_{BL} = \begin{bmatrix} 1 & -1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 & -1 & 1 \end{bmatrix}, \end{aligned}$$

are used because of space limitations; ordinarily a researcher would use many more blocks. The null hypotheses for treatment A and blocks are, respectively,

$$\begin{array}{ll} H_0: \mu_{1\cdot} - \mu_{2\cdot} = 0 & H_0: \mu_{1\cdot} - \mu_{2\cdot} = 0 \\ \mu_{2\cdot} - \mu_{3\cdot} = 0 & \mu_{2\cdot} - \mu_{3\cdot} = 0 \\ \mu_{3\cdot} - \mu_{4\cdot} = 0 & \mu_{3\cdot} - \mu_{4\cdot} = 0 \end{array} \quad (13)$$

In matrix notation, the hypotheses can be written as

$$\begin{array}{ccc} \text{Hypothesis} & \text{Mean} & \text{Null} \\ \text{matrix} & \text{vector} & \text{vector} \\ \mathbf{H}'_A & \begin{bmatrix} \mu_A \\ \mu_{1\cdot} \\ \mu_{2\cdot} \\ \mu_{3\cdot} \end{bmatrix} & \begin{bmatrix} \mathbf{0}_A \\ 0 \\ 0 \\ 0 \end{bmatrix} \end{array}$$

$$\begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} \mu_{1\cdot} \\ \mu_{2\cdot} \\ \mu_{3\cdot} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

where $\mathbf{1}'_{BL}$ is a $1 \times n$ vector of ones and $\mathbf{1}'_A$ is a $1 \times p$ vector of ones. The null hypothesis for treatment A can be expressed as $1/n \mathbf{C}'_A \boldsymbol{\mu} = \mathbf{0}_A$, where $\boldsymbol{\mu}$ is an $h \times 1$ vector of population means and $\mathbf{0}_A$ is a $(p-1) \times 1$ vector of zeros. The restrictions on the model, $\mu_{ij} - \mu_{i'j} - \mu_{ij'} + \mu_{i'j'} = 0$ for all i, i', j , and j' , can be expressed as $\mathbf{R}' \boldsymbol{\mu} = \boldsymbol{\theta}_A$, where $\boldsymbol{\theta}_A$ is an $s = h - p - n + 1$ vector of zeros. Without any loss of generality, the fractions in the $1/n \mathbf{C}'_A$ and $1/p \mathbf{C}'_{BL}$ matrices can be eliminated by replacing the fractions with 1 and -1 . To test $\mathbf{C}'_A \boldsymbol{\mu} = \mathbf{0}_A$ subject to the restrictions that $\mathbf{R}' \boldsymbol{\mu} = \boldsymbol{\theta}_A$, we can form an augmented treatment matrix and an augmented vector of zeros as follows:

$$\mathbf{Q}'_A = \begin{bmatrix} \mathbf{R}' \\ \mathbf{C}'_A \end{bmatrix} \quad \boldsymbol{\eta}_A = \begin{bmatrix} \boldsymbol{\theta}_A \\ \mathbf{0}_A \end{bmatrix}, \quad (16)$$

4 Analysis of Variance: Cell Means Approach

where $\mathbf{Q}'_A$ consists of the s rows of the $\mathbf{R}'$ matrix and the $p - 1$ rows of the $\mathbf{C}'_A$ matrix that are not identical to the rows of $\mathbf{R}'$, inconsistent with them, or linearly dependent on them and $\boldsymbol{\eta}_A$ is an $s + p - 1$ vector of zeros. The joint null hypothesis $\mathbf{Q}'_A \boldsymbol{\mu} = \boldsymbol{\eta}_A$ combines the restrictions that all interactions are equal to zero with the hypothesis that differences among the treatment means are equal to zero. The sum of squares that is used to test this joint null hypothesis is

$$SSA = (\mathbf{Q}'_A \hat{\boldsymbol{\mu}})' (\mathbf{Q}'_A \mathbf{Q}_A)^{-1} (\mathbf{Q}'_A \hat{\boldsymbol{\mu}}) - SSRES, \quad (17)$$

where $SSRES = (\mathbf{R}' \hat{\boldsymbol{\mu}})' (\mathbf{R}' \mathbf{R})^{-1} (\mathbf{R}' \hat{\boldsymbol{\mu}})$. To test hypotheses about contrasts among treatment means, restricted cell means rather than unrestricted cell means should be used. The vector of restricted cell means, $\hat{\boldsymbol{\mu}}_R$, is given by

$$\hat{\boldsymbol{\mu}}_R = \hat{\boldsymbol{\mu}} - \mathbf{R}(\mathbf{R}' \mathbf{R})^{-1} \mathbf{R}' \hat{\boldsymbol{\mu}}. \quad (18)$$

The formula for computing the sum of squares for blocks follows the pattern described earlier for treatment A . We want to test the null hypothesis for blocks, $\mathbf{C}'_{BL} \boldsymbol{\mu} = \mathbf{0}_{BL}$, subject to the restrictions that $\mathbf{R}' \boldsymbol{\mu} = \boldsymbol{\theta}_{BL}$. We can form an augmented matrix for blocks and an augmented vector of zeros as follows:

$$\mathbf{Q}'_{BL} = \begin{bmatrix} \mathbf{R}' \\ \mathbf{C}'_{BL} \end{bmatrix} \quad \boldsymbol{\eta}_{BL} = \begin{bmatrix} \boldsymbol{\theta}_{BL} \\ \mathbf{0}_{BL} \end{bmatrix}, \quad (19)$$

where $\mathbf{Q}'_{BL}$ consists of the s rows of the $\mathbf{R}'$ matrix and the $n - 1$ rows of the $\mathbf{C}'_{BL}$ matrix that are not identical to the rows of $\mathbf{R}'$, inconsistent with them, or linearly dependent on them, and $\boldsymbol{\eta}_{BL}$ is an $s + n - 1$ vector of zeros. The joint null hypothesis $\mathbf{Q}'_{BL} \boldsymbol{\mu} = \boldsymbol{\eta}_{BL}$ combines the restrictions that all interactions are equal to zero with the hypothesis that differences among the block means are equal to zero. The sum of squares that is used to test this joint null hypothesis is

$$SSBL = (\mathbf{Q}'_{BL} \hat{\boldsymbol{\mu}})' (\mathbf{Q}'_{BL} \mathbf{Q}_{BL})^{-1} (\mathbf{Q}'_{BL} \hat{\boldsymbol{\mu}}) - SSRES. \quad (20)$$

The total sum of squares is given by

$$SSTOTAL = \hat{\boldsymbol{\mu}}' \hat{\boldsymbol{\mu}} - \hat{\boldsymbol{\mu}}' \hat{\mathbf{J}} \hat{\boldsymbol{\mu}} h^{-1}. \quad (21)$$

The treatment and block mean squares are given by, respectively, $MSA = SSA/(p - 1)$ and $MSBL = SSBL/[(n - 1)(p - 1)]$. The F statistics are $F = MSA/MSRES$ and $F = MSBL/MSRES$.

The previous paragraphs have provided an overview of the restricted cell means model. For many restricted models, the formulas for computing SSA and $SSBL$ can be simplified. The simplified formulas are described by Kirk [2, pp. 290–297]. An important advantage of the cell means model is that it can be used when observations are missing; the procedures for a randomized block design are described by Kirk [2, pp. 297–301]. Another advantage of the cell means model that we will illustrate in the following section is that it can be used when there are empty cells in a multitreatment design.

Unrestricted Cell Means Model for a Completely Randomized Factorial Design

The expectation of the classical sum of squares model equation for a two-treatment, completely randomized factorial design is

$$E(Y_{ijk}) = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk}$$

$$(i = 1, \dots, n; j = 1, \dots, p; k = 1, \dots, q), \quad (22)$$

where Y_{ijk} is the observation for participant i in treatment combination $a_j b_k$, μ is the grand mean, α_j is the treatment effect for population j , β_k is the treatment effect for population k , and $(\alpha\beta)_{jk}$ is the interaction of treatment levels j and k . If treatments A and B each have three levels, the classical model contains 16 parameters: $\mu, \alpha_1, \alpha_2, \alpha_3, \beta_1, \beta_2, \beta_3, (\alpha\beta)_{11}, (\alpha\beta)_{12}, \dots, (\alpha\beta)_{33}$. However, only nine cell means are available to estimate these parameters. Thus, the model is overparameterized – it contains more parameters than there are means from which to estimate them. Statisticians have developed a number of ways to get around this problem [4, 5, 8]. Unfortunately, the solutions do not work well when there are missing observations or empty cells.

The cell means model equation for a two-treatment, completely randomized factorial design is

$$Y_{ijk} = \mu_{jk} + \varepsilon_{i(jk)} \quad (i = 1, \dots, n; j = 1, \dots, p; k = 1, \dots, q), \quad (23)$$

where μ_{jk} is the population mean for treatment combination $a_j b_k$ and $\varepsilon_{i(jk)}$ is the error effect that is i.i.d. $N(0, \sigma_e^2)$. This model has none of the problems associated with overparameterization. A population mean can be estimated for each cell that contains

one or more observations. Thus, the model is fully parameterized. And unlike the classical ANOVA model, the cell means model does not impose a structure on the analysis of data. Consequently, the model can be used to test hypotheses about any linear combination of cell means. It is up to the researcher to decide which tests are meaningful or useful based on the original research hypotheses, the way the experiment was conducted, and the data that are available. As we will show, however, if one or more cells are empty, linear combinations of cell means must be carefully chosen because some tests may be uninterpretable.

An experiment described by Kirk [2, pp. 367–370] is used to illustrate the computational procedures for the cell means model. The experiment examined the effects of $p = 3$ levels of treatments A and $q = 3$ levels of treatment B on $N = 45$ police recruits' attitudes toward minorities. The attitude data are shown in Table 2.

Using matrices and vectors, the null hypotheses for treatments A and B can be expressed as

$$\begin{aligned} \mathbf{H}'_A \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} \mu_A \\ \mu_{1.} \\ \mu_{2.} \\ \mu_{3.} \end{bmatrix} &= \begin{bmatrix} 0_A \\ 0 \end{bmatrix} \\ \mathbf{H}'_B \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} \mu_B \\ \mu_{.1} \\ \mu_{.2} \\ \mu_{.3} \end{bmatrix} &= \begin{bmatrix} 0_B \\ 0 \end{bmatrix}. \end{aligned} \quad (24)$$

The formulas for computing the sums of squares are

$$SSTOTAL = \mathbf{y}'\mathbf{y} - \mathbf{y}'\mathbf{J}\mathbf{y}N^{-1}$$

$$SSA = (\mathbf{C}'_A \hat{\boldsymbol{\mu}})'[\mathbf{C}'_A(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}_A]^{-1}(\mathbf{C}'_A \hat{\boldsymbol{\mu}})$$

$$SSB = (\mathbf{C}'_B \hat{\boldsymbol{\mu}})'[\mathbf{C}'_B(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}_B]^{-1}(\mathbf{C}'_B \hat{\boldsymbol{\mu}})$$

$$SSA \times B = (\mathbf{C}'_{AB} \hat{\boldsymbol{\mu}})'[\mathbf{C}'_{AB}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}_{AB}]^{-1}(\mathbf{C}'_{AB} \hat{\boldsymbol{\mu}})$$

$$SSWCELL = \mathbf{y}'\mathbf{y} - \hat{\boldsymbol{\mu}}'\mathbf{X}'\mathbf{y}, \quad (25)$$

where $\mathbf{y}$ is an $N \times 1$ vector of observations and $\mathbf{X}$ is an $N \times pq$ structural matrix that indicates the treatment level in which an observation appears. For the data in Table 2, $\mathbf{y}$ and $\mathbf{X}$ are

$$\begin{aligned} \mathbf{y} &= \begin{bmatrix} 24 \\ 33 \\ 37 \\ 29 \\ 42 \\ 44 \\ 36 \\ 25 \\ 27 \\ 43 \\ \vdots \\ 42 \\ 52 \\ 53 \\ 49 \\ 64 \end{bmatrix} \\ \mathbf{X} &= \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \end{aligned}$$

$\mathbf{J}$ is an $N \times N$ matrix of ones. $\hat{\boldsymbol{\mu}}$ is a $pq \times 1$ vector of sample means and is given by $\hat{\boldsymbol{\mu}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} = [33, 35, 38, 30, 31, \dots, 52]'$. The coefficient matrices for computing sums of squares are obtained using Kronecker products as follows:

$$\begin{aligned} \mathbf{H}'_A \otimes \frac{1}{q}\mathbf{1}'_B &= \frac{1}{q} \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \otimes \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} = \frac{1}{q} \begin{bmatrix} 1 & 1 & 1 & -1 & -1 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & -1 & -1 & -1 \end{bmatrix} \\ \frac{1}{p}\mathbf{1}'_A \otimes \mathbf{H}'_B &= \frac{1}{p} \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \otimes \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} = \frac{1}{p} \begin{bmatrix} 1 & -1 & 0 & 1 & -1 & 0 & 1 & -1 & 0 \\ 0 & 1 & -1 & 0 & 1 & -1 & 0 & 1 & -1 \end{bmatrix} \\ \mathbf{H}'_A \otimes \mathbf{H}'_B &= \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \otimes \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & -1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 & 0 & -1 & 1 \end{bmatrix}. \end{aligned} \quad (26)$$

6 Analysis of Variance: Cell Means Approach

Table 2 Attitude data for 45 police recruits

a_1 b_1	a_1 b_2	a_1 b_3	a_2 b_1	a_2 b_2	a_2 b_3	a_3 b_1	a_3 b_2	a_3 b_3
24	44	38	30	35	26	21	41	42
33	36	29	21	40	27	18	39	52
37	25	28	39	27	36	10	50	53
29	27	47	26	31	46	31	36	49
42	43	48	34	22	45	20	34	64
$\sum_{i=1}^n \bar{Y}_{.jk} =$								
33	35	38	30	31	36	20	40	52

Without any loss of generality, the fractions in $1/q\mathbf{C}'_A$ and $1/p\mathbf{C}'_B$ can be eliminated by replacing the fractions with 1 and -1 . The sums of squares and mean squares for the data in Table 2 are

$$\begin{aligned}
 SSA &= 190.000 & MSA &= \frac{95.000}{(3-1)} = 95.000 \\
 SSB &= 1543.333 & MSB &= \frac{1543.333}{(3-1)} = 771.667 \\
 SSA \times B &= 1236.667 & MSA \times B &= \frac{1236.667}{(3-1)(3-1)} \\
 & & &= 309.167 \\
 SSWCELL &= 2250.000 & MSWCELL &= \frac{2250.000}{(45-9)} \\
 & & &= 62.500 \\
 SSTOTAL &= 5220.000 & & (27)
 \end{aligned}$$

The F statistics and P values for treatments A and B , and the $A \times B$ interaction are, respectively, $F = MSA/MSWCELL = 1.52$, $p = .23$; $F = MSB/MSWCELL = 12.35$, $p < .0001$; $F = MSA \times B/MSWCELL = 4.95$, $p = .003$.

Because the $A \times B$ interaction is significant, some researchers would perform tests of simple main-effects (see **Interaction Effects**). The computations are easy to perform with the cell means model. The null hypothesis for the simple main-effects of treatment A at b_1 , for example, is

$$\begin{aligned}
 H_0: \mu_{11} - \mu_{21} &= 0 \\
 \mu_{21} - \mu_{31} &= 0.
 \end{aligned} \quad (28)$$

The coefficient matrix for computing the sums of squares of treatment A at b_1 is obtained using the

Kronecker product as follows:

$$\begin{aligned}
 &\mathbf{H}'_A \\
 &\begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \otimes \begin{bmatrix} \mathbf{c}'_{A \text{ at } b_1} \\ 1 & 0 & 0 \end{bmatrix} \\
 &\mathbf{C}'_{A \text{ at } b_1} \\
 &= \begin{bmatrix} 1 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & -1 & 0 & 0 \end{bmatrix}. \quad (29)
 \end{aligned}$$

The coefficient vector $\mathbf{c}'_{A \text{ at } b_1} = [1 \ 0 \ 0]$ selects the first level of treatment B . The second level of treatment B can be selected by using the coefficient vector $\mathbf{C}'_{A \text{ at } b_2} = [0 \ 1 \ 0]$, and so on. The simple main-effects sums of squares of treatment A at b_1 is

$$\begin{aligned}
 SSA \text{ at } b_1 &= (\mathbf{C}'_{A \text{ at } b_1} \hat{\boldsymbol{\mu}})' [\mathbf{C}'_{A \text{ at } b_1} (\mathbf{X}'\mathbf{X})^{-1} \mathbf{C}_{A \text{ at } b_1}]^{-1} \\
 &\times (\mathbf{C}'_{A \text{ at } b_1} \hat{\boldsymbol{\mu}}) = 463.3333. \quad (30)
 \end{aligned}$$

The F statistic and Bonferroni adjusted P value [2, p. 381] are $F = [SSA \text{ at } b_1 / (p-1)] / MSWCELL = 231.167 / 62.500 = 3.71$, $p > .05$.

When the $A \times B$ interaction is significant, rather than performing tests of simple main-effects, we prefer to test treatment-contrast interactions and contrast-contrast interactions. The significant $A \times B$ interaction indicates that at least one contrast for the treatment B means interacts with treatment A and vice versa. Suppose that after examining the data, we want to determine if the treatment B contrast denoted by $\psi_{1(B)}$ interacts with treatment A , where $\psi_{1(B)} = \mathbf{c}'_{1(B)} \boldsymbol{\mu}_B$ and $\mathbf{c}'_{1(B)} = [1 \ -1 \ 0]$. The null hypothesis is $H_0: \alpha \times \psi_{1(B)} = \delta$ for all j , where δ is a constant for a given hypothesis. The coefficient matrix for computing the sum of squares for this treatment-contrast interaction is as follows:

$$\begin{aligned}
 &\mathbf{H}'_A \\
 &\begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \otimes \begin{bmatrix} \mathbf{c}'_{1(B)} \\ 1 & -1 & 0 \end{bmatrix} \\
 &\mathbf{C}'_{A \times \psi_{1(B)}} \\
 &= \begin{bmatrix} 1 & -1 & 0 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 & -1 & 1 & 0 \end{bmatrix}. \quad (31)
 \end{aligned}$$

The treatment-contrast interaction sum of squares is

$$\begin{aligned}
 SSA \psi_B &= (\mathbf{C}'_{A \times \psi_{1(B)}} \hat{\boldsymbol{\mu}})' [\mathbf{C}'_{A \times \psi_{1(B)}} (\mathbf{X}'\mathbf{X})^{-1} \mathbf{C}_{A \times \psi_{1(B)}}]^{-1} \\
 &\times (\mathbf{C}'_{A \times \psi_{1(B)}} \hat{\boldsymbol{\mu}}) = 571.6667. \quad (32)
 \end{aligned}$$

The F statistic and simultaneous test procedure adjusted P value [2, p. 381] are $F = [SSA \psi_B / (p -$

1)]/MSWCELL = 285 833/62.500 = 4.57, $p > .05$. Because the test is not significant, the null hypothesis that $\alpha \times \psi_{1(B)} = \delta$ for all j remains tenable.

Cell Means Model with Missing Observations and Empty Cells

The cell means model is especially useful for analyzing data when the cell n_{jk} 's are unequal and one or more cells are empty. A researcher can test hypotheses about any linear combination of population means that can be estimated from the data. The challenge facing the researcher is to formulate interesting and interpretable null hypotheses using the means that are available.

Suppose that for reasons unrelated to the treatments, observation Y_{511} in Table 2 is missing. When the cell n_{jk} 's are unequal, the researcher has a choice between computing unweighted means, μ , or weighted means, $\bar{\mu}$ (see **Analysis of Variance: Multiple Regression Approaches**). Unweighted means are simple averages of cell means. Hypotheses for these means were described in the previous section. For treatments A and B , the means are given by, respectively,

$$\mu_{j\cdot} = \sum_{k=1}^q \frac{\mu_{jk}}{q} \text{ and } \mu_{\cdot k} = \sum_{j=1}^p \frac{\mu_{jk}}{p}. \quad (33)$$

general, the use of weighted means is not recommended unless the sample n_{jk} 's are proportional to the population n_{jk} 's.

For the case in which observation Y_{511} in Table 2 is missing, null hypotheses for treatment A using unweighted and weighted means are, respectively,

$$\begin{aligned} H_0: \frac{\mu_{11} + \mu_{12} + \mu_{13}}{3} - \frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} &= 0 \\ \frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} - \frac{\mu_{31} + \mu_{32} + \mu_{33}}{3} &= 0 \end{aligned} \quad (35)$$

and

$$\begin{aligned} H_0: \frac{4\mu_{11} + 5\mu_{12} + 5\mu_{13}}{14} \\ - \frac{5\mu_{21} + 5\mu_{22} + 5\mu_{23}}{15} &= 0 \\ \frac{5\mu_{21} + 5\mu_{22} + 5\mu_{23}}{15} - \frac{5\mu_{31} + 5\mu_{32} + 5\mu_{33}}{15} &= 0. \end{aligned} \quad (36)$$

The coefficients of the unweighted means are $\pm 1/q$ and 0; the coefficients of the weighted means are $\pm n_{jk}/n_j$ and 0. The unweighted and weighted coefficient matrices and sums of squares are, respectively,

$$\begin{aligned} \mathbf{C}'_{1(A)} &= \begin{bmatrix} 1/3 & 1/3 & 1/3 & -1/3 & -1/3 & -1/3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/3 & 1/3 & 1/3 & -1/3 & -1/3 & -1/3 \end{bmatrix} \\ SSA &= (\mathbf{C}'_{1(A)}\hat{\boldsymbol{\mu}})'[\mathbf{C}'_{1(A)}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}_{1(A)}]^{-1}(\mathbf{C}'_{1(A)}\hat{\boldsymbol{\mu}}) = 188.09 \\ \mathbf{C}'_{2(A)} &= \begin{bmatrix} 4/14 & 5/14 & 5/14 & -5/15 & -5/15 & -5/15 & 0 & 0 & 0 \\ 0 & 0 & 0 & 5/15 & 5/15 & 5/15 & -5/15 & -5/15 & -5/15 \end{bmatrix} \\ SSA &= (\mathbf{C}'_{2(A)}\hat{\boldsymbol{\mu}})'[\mathbf{C}'_{2(A)}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}_{2(A)}]^{-1}(\mathbf{C}'_{2(A)}\hat{\boldsymbol{\mu}}) = 187.51 \end{aligned} \quad (37)$$

Weighted means are weighted averages of cell means in which the weights are the sample n_{jk} 's,

$$\bar{\mu}_{j\cdot} = \sum_{k=1}^q \frac{n_{jk}\mu_{jk}}{n_{j\cdot}} \text{ and } \bar{\mu}_{\cdot k} = \sum_{j=1}^p \frac{n_{jk}\mu_{jk}}{n_{\cdot k}}. \quad (34)$$

The value of weighted means is affected by the sample n_{jk} 's. Hence, the means are data dependent. In

with 2 degrees of freedom, the number of rows in $\mathbf{C}'_{1(A)}$ and $\mathbf{C}'_{2(A)}$.

Null hypotheses for treatment B using unweighted and weighted means are, respectively,

$$H_0: \frac{\mu_{11} + \mu_{21} + \mu_{31}}{3} - \frac{\mu_{12} + \mu_{22} + \mu_{32}}{3} = 0$$

8 Analysis of Variance: Cell Means Approach

$$\frac{\mu_{12} + \mu_{22} + \mu_{32}}{3} - \frac{\mu_{13} + \mu_{23} + \mu_{33}}{3} = 0 \quad (38)$$

and

$$\begin{aligned} H_0: & \frac{4\mu_{11} + 5\mu_{21} + 5\mu_{31}}{14} \\ & - \frac{5\mu_{12} + 5\mu_{22} + 5\mu_{32}}{15} = 0 \\ & \frac{5\mu_{12} + 5\mu_{22} + 5\mu_{32}}{15} - \frac{5\mu_{13} + 5\mu_{23} + 5\mu_{33}}{15} = 0. \end{aligned} \quad (39)$$

The coefficients of the unweighted means are $\pm 1/p$ and 0; the coefficients of the weighted means are $\pm n_{jk}/n_{\cdot k}$ and 0. The unweighted and weighted coefficient matrices and sums of squares are, respectively,

$$\begin{aligned} \mathbf{C}'_{1(B)} &= \begin{bmatrix} 1/3 & -1/3 & 0 & 1/3 & -1/3 & 0 & 1/3 & -1/3 & 0 \\ 0 & 1/3 & -1/3 & 0 & 1/3 & -1/3 & 0 & 1/3 & -1/3 \end{bmatrix} \\ SSB &= (\mathbf{C}'_{1(B)}\hat{\boldsymbol{\mu}})'[\mathbf{C}'_{1(B)}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}_{1(B)}]^{-1}(\mathbf{C}'_{1(B)}\hat{\boldsymbol{\mu}}) = 1649.29 \\ \mathbf{C}'_{2(B)} &= \begin{bmatrix} 4/14 & -5/15 & 0 & 5/14 & -5/15 & 0 & 5/14 & -5/15 & 0 \\ 0 & 5/15 & -5/15 & 0 & 5/15 & -5/15 & 0 & 5/15 & -5/15 \end{bmatrix} \\ SSB &= (\mathbf{C}'_{2(B)}\hat{\boldsymbol{\mu}})'[\mathbf{C}'_{2(B)}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}_{2(B)}]^{-1}(\mathbf{C}'_{2(B)}\hat{\boldsymbol{\mu}}) = 1713.30, \end{aligned} \quad (40)$$

with 2 degrees of freedom, the number of rows in $\mathbf{C}'_{1(B)}$ and $\mathbf{C}'_{2(B)}$.

When one or more cells are empty, the analysis of the data is more challenging. Consider the police attitude data in Table 3 where an observation Y_{511}

Table 3 Police recruit attitude data, observation Y_{511} is missing and cells a_1b_3 and a_2b_2 are empty

a_1 b_1	a_1 b_2	a_1 b_3	a_2 b_1	a_2 b_2	a_2 b_3	a_3 b_1	a_3 b_2	a_3 b_3
24	44		30		26	21	41	42
33	36		21		27	18	39	52
37	25		39		36	10	50	53
29	27		26		46	31	36	49
	43		34		45	20	34	64
$\sum_{i=1}^n \bar{Y}_{jk} = 30.75$	35		30		36	20	40	52

in cell a_1b_1 is missing and cells a_1b_3 and a_2b_2 are empty. The experiment was designed to test along with other hypotheses, the following null hypothesis for treatment A

$$\begin{aligned} H_0: & \frac{\mu_{11} + \mu_{12} + \mu_{13}}{3} - \frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} = 0 \\ & \frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} - \frac{\mu_{31} + \mu_{32} + \mu_{33}}{3} = 0. \end{aligned} \quad (41)$$

Unfortunately, this hypothesis is untestable because μ_{13} and μ_{22} cannot be estimated. The hypothesis

$$\begin{aligned} H_0: & \frac{\mu_{11} + \mu_{12}}{2} - \frac{\mu_{21} + \mu_{23}}{2} = 0 \\ & \frac{\mu_{21} + \mu_{23}}{2} - \frac{\mu_{31} + \mu_{32} + \mu_{33}}{3} = 0 \end{aligned} \quad (42)$$

is testable because data are available to estimate each of the population means. However, the hypothesis is uninterpretable because different levels of treatment B appear in each row: (b_1 and b_2) versus (b_1 and b_3) in the first row and (b_1 and b_3) versus (b_1 , b_2 , and b_3) in the second row. The following hypothesis is both testable and interpretable.

$$\begin{aligned} H_0: & \frac{\mu_{11} + \mu_{12}}{2} - \frac{\mu_{31} + \mu_{32}}{2} = 0 \\ & \frac{\mu_{21} + \mu_{23}}{2} - \frac{\mu_{31} + \mu_{33}}{2} = 0. \end{aligned} \quad (43)$$

For a hypothesis to be interpretable, the estimators of population means for each contrast in the hypothesis should share the same levels of the other treatment(s). For example, to estimate $\mu_{1\cdot} = 1/2(\mu_{11} + \mu_{12})$ and $\mu_{3\cdot} = 1/2(\mu_{31} + \mu_{32})$, it is necessary to average over b_1 and b_2 and ignore b_3 . The

null hypothesis for treatment A can be expressed in matrix notation as $\mathbf{C}'_A \boldsymbol{\mu} = \mathbf{0}$, where

$$\mathbf{C}'_A = \begin{bmatrix} 1/2 & 1/2 & 0 & 0 & -1/2 & -1/2 & 0 \\ 0 & 0 & 1/2 & 1/2 & -1/2 & 0 & -1/2 \end{bmatrix}$$

$$\boldsymbol{\mu}' = [\mu_{11} \ \mu_{12} \ \mu_{21} \ \mu_{23} \ \mu_{31} \ \mu_{32} \ \mu_{33}]. \quad (44)$$

The fractions in $\mathbf{C}'_A$ can be eliminated by replacing the fractions with 1 and -1 . For the data in Table 3 where Y_{511} is missing and two of the cells are empty, the sum of squares for testing (43) is

$$SSA = (\mathbf{C}'_A \hat{\boldsymbol{\mu}})' [\mathbf{C}'_A (\mathbf{X}'\mathbf{X})^{-1} \mathbf{C}_A]^{-1} (\mathbf{C}'_A \hat{\boldsymbol{\mu}}) = 110.70 \quad (45)$$

with 2 degrees of freedom, the number of rows in $\mathbf{C}'_A$.

Testable and interpretable hypotheses for treatment B and the $A \times B$ interaction are, respectively,

$$H_0: \frac{1}{2}(\mu_{11} + \mu_{31}) - \frac{1}{2}(\mu_{12} + \mu_{32}) = 0 \quad (\text{Treatment } B)$$

$$\frac{1}{2}(\mu_{21} + \mu_{31}) - \frac{1}{2}(\mu_{23} + \mu_{33}) = 0 \quad (46)$$

and

$$H_0: \mu_{11} - \mu_{31} - \mu_{12} + \mu_{32} = 0 \quad (A \times B \text{ interaction})$$

$$\mu_{21} - \mu_{31} - \mu_{23} + \mu_{33} = 0. \quad (47)$$

If there were no empty cells, the null hypothesis for the $A \times B$ interaction would have $h - p - q + 1 = 9 - 3 - 3 + 1 = 4$ interaction terms. However, because of the empty cells, only two of the interaction terms can be tested. If the null hypothesis for the $A \times B$ interaction is rejected, we can conclude that at least one function of the form $\mu_{jk} - \mu_{j'k} - \mu_{jk'} + \mu_{j'k'}$ does not equal zero. However, failure to reject the null hypothesis does not imply that all functions of the form $\mu_{jk} - \mu_{j'k} - \mu_{jk'} + \mu_{j'k'}$ equal zero because we are unable to test two of the interaction terms.

When cells are empty, it is apparent that to test hypotheses, the researcher must be able to state the hypotheses in terms of linearly independent contrasts in $\mathbf{C}'\boldsymbol{\mu}$. Thus, the researcher is forced to consider what hypotheses are both interesting and interpretable. This is not the case when the classical

ANOVA model is used. When this model is used, the hypotheses that are tested are typically left to a computer package, and the researcher is seldom aware of exactly what hypotheses are being tested.

Unrestricted Cell Means Model for ANCOVA

The cell means model can be used to perform an **analysis of covariance** (ANCOVA). This application of the model is described using a completely randomized ANCOVA design with N observations, p treatment levels, and one covariate. The adjusted between-groups sum of squares, A_{adj} , and the adjusted within-groups sum of squares, E_{adj} , for a completely randomized ANCOVA design are given by

$$A_{adj} = (A_{yy} + E_{yy}) - \frac{(A_{zy} + E_{zy})^2}{A_{zz} + E_{zz}} - E_{adj} \text{ and}$$

$$E_{adj} = E_{yy} - \frac{(E_{zy})^2}{E_{zz}}. \quad (48)$$

The sums of squares in the formula, A_{yy} , E_{yy} , A_{zy} , and so on, can be expressed in matrix notation using the cell means model by defining

$$\begin{aligned} A_{yy} &= (\mathbf{C}'_A \hat{\boldsymbol{\mu}}_y)' (\mathbf{C}'_A (\mathbf{X}'\mathbf{X})^{-1} \mathbf{C}_A)^{-1} (\mathbf{C}'_A \hat{\boldsymbol{\mu}}_y) \\ A_{zy} &= (\mathbf{C}'_A \hat{\boldsymbol{\mu}}_z)' (\mathbf{C}'_A (\mathbf{X}'\mathbf{X})^{-1} \mathbf{C}_A)^{-1} (\mathbf{C}'_A \hat{\boldsymbol{\mu}}_y) \\ A_{zz} &= (\mathbf{C}'_A \hat{\boldsymbol{\mu}}_z)' (\mathbf{C}'_A (\mathbf{X}'\mathbf{X})^{-1} \mathbf{C}_A)^{-1} (\mathbf{C}'_A \hat{\boldsymbol{\mu}}_z) \\ \hat{\boldsymbol{\mu}}_y &= (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{y} \\ \hat{\boldsymbol{\mu}}_z &= (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{z} \\ E_{yy} &= \mathbf{y}'\mathbf{y} - \hat{\boldsymbol{\mu}}_y' \mathbf{X}'\mathbf{y} \\ E_{zy} &= \mathbf{z}'\mathbf{y} - \hat{\boldsymbol{\mu}}_z' \mathbf{X}'\mathbf{y} \\ E_{zz} &= \mathbf{z}'\mathbf{z} - \hat{\boldsymbol{\mu}}_z' \mathbf{X}'\mathbf{z}, \end{aligned} \quad (49)$$

where $\hat{\boldsymbol{\mu}}_y$ is a $p \times 1$ vector of dependent variable cell means, $\mathbf{X}$ is a $N \times p$ structural matrix, $\hat{\boldsymbol{\mu}}_z$ is a $p \times 1$ vector of covariate means, $\mathbf{y}$ is an $N \times 1$ vector of dependent variable observations, and $\mathbf{z}$ is an $N \times 1$ vector of covariates. The adjusted between- and within-groups mean squares are given by, respectively,

$$MSA_{adj} = \frac{A_{adj}}{(p-1)} \text{ and } MSE_{adj} = \frac{E_{adj}}{(N-p-1)}. \quad (50)$$

The F statistic is $F = MSA_{adj}/MSE_{adj}$ with $p - 1$ and $N - p - 1$ degrees of freedom.

The cell means model can be extended to other ANCOVA designs and to designs with multiple covariates (see **Analysis of Covariance**). Lack of space prevents a description of the computational procedures.

Some Advantages of the Cell Means Model

The simplicity of the cell means model is readily apparent. There are only two models for all ANOVA designs: an unrestricted model and a restricted model. Furthermore, only three kinds of computational formulas are required to compute all sums of squares: treatment and interaction sums of squares have the general form $(\mathbf{C}'\hat{\boldsymbol{\mu}})'[\mathbf{C}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{C}]^{-1}(\mathbf{C}'\hat{\boldsymbol{\mu}})$, the within-groups and within-cells sums of squares have the form $\mathbf{y}'\mathbf{y} - \hat{\boldsymbol{\mu}}'\mathbf{X}'\mathbf{y}$, and the total sum of squares has the form $\mathbf{y}'\mathbf{y} - \mathbf{y}'\mathbf{J}\mathbf{y}N^{-1}$.

The cell means model has an important advantage relative to the classical overparameterized model: the ease with which experiments with missing observations and empty cells can be analyzed. In the classical model, questions arise regarding which functions are estimable and which hypotheses are testable. However, these are nonissues with the cell means model. There is never any confusion about what functions of the means are estimable and what their best linear unbiased estimators are. And it is easy to discern which hypotheses are testable. Furthermore, the cell means model is always of full rank with the $\mathbf{X}'\mathbf{X}$ matrix being a diagonal matrix whose elements are the cell sample sizes. The number of parameters in the model exactly equals the number of cells that contain one or more observations.

There is never any confusion about what null hypotheses are tested by treatment and interaction

mean squares. The researcher specifies the hypothesis of interest when the contrasts in $\mathbf{C}'\boldsymbol{\mu}$ are specified. Hence, a sample representation of the null hypothesis always appears in formulas for treatment and interaction mean squares. Finally, the cell means model gives the researcher great flexibility in analyzing data because hypotheses about any linear combination of available cell means can be tested (see **Multiple Comparison Procedures**).

Analysis of Variance: Classification

A variety of **analysis of variance (ANOVA)** designs are available to researchers. Unfortunately, there is no standard nomenclature for the designs. For example, the simplest ANOVA design is variously referred to as a completely randomized design, one-way classification design, single-factor experiment, randomized group design, simple randomized design, single variable experiment, and one-way ANOVA. The use of multiple designations for designs is confusing. In this article, I describe a nomenclature and acronyms for ANOVA designs that are based on three simple ANOVA designs. These designs—completely randomized design, **randomized block design**, and **Latin square design**—are the building blocks with which more complex designs are constructed. Four characteristics of the designs are described: layout of the designs, partition of the total sum of squares and degrees of freedom, hypotheses that can be tested, and advantages and disadvantages of the designs. To simplify the presentation, I assume that all treatment levels of interest are included in the designs, that is, a fixed-effects model is appropriate. Space limitations prevent me from describing the computational procedures or the assumptions associated with the designs. For this information, the reader is referred to the many excellent experimental design books [1, 2, 4, 6, 7, 9–12].

Completely Randomized Design

The simplest ANOVA design in terms of assignment of participants (experimental units) to treatment levels and the statistical analysis of data is called a **completely randomized design**. The design is appropriate for experiments that have one treatment with $p \geq 2$ treatment levels. I use the terms ‘treatment,’ ‘factor,’ and ‘independent variable’ interchangeably. A treatment is identified by the capital letter A . A specific level of treatment A is denoted by the lower case letter a and a number or letter subscript, for example, $a_1, a_2, \dots, a_p$. A particular but unspecified treatment level is denoted by a_j where j ranges over the values $1, \dots, p$. In a completely randomized design, N participants are randomly assigned to the p levels

of the treatment. It is desirable to assign an equal or approximately equal number of participants, n_j , to each treatment level [10]. The abbreviated designation for a completely randomized design is CR- p , where CR stands for ‘completely randomized’ and p denotes the number of treatment levels.

Consider an experiment to evaluate three therapies for helping cigarette smokers break the habit. The designations for the three treatment levels are: a_1 = cognitive-behavioral therapy, a_2 = hypnosis, and a_3 = drug therapy. The dependent variable could be the number of participants who are no longer smoking after six months of treatment, the change in their cigarette consumption, or any one of a number of other measures.

Assume that $N = 45$ smokers who want to stop are available to participate in the experiment. The 45 smokers are randomly assigned to the three treatment levels with the restriction that $n = 15$ smokers are assigned to each level. The phrase ‘randomly assigned’ is important. Random assignment (see **Randomization**) helps to distribute the idiosyncratic characteristics of the participants over the three treatment levels so that the characteristics do not selectively bias the outcome of the experiment. If, for example, a disproportionately large number of very heavy smokers was assigned to one of the treatment levels, the comparison of this therapy with the other therapies could be compromised. The **internal validity** of a completely randomized design depends on random assignment.

The layout for the CR-3 design is shown in Figure 1. The partition of the total sum of squares, $SSTOTAL$, and total degrees of freedom, $np - 1$, are as follows:

$$\begin{aligned} SSTOTAL &= SSBG + SSWG \\ np - 1 &= p - 1 + p(n - 1), \end{aligned} \quad (1)$$

where $SSBG$ denotes the between-groups sum of squares and $SSWG$ denotes the within-groups sum of squares. The null hypothesis is $H_0: \mu_1 = \mu_2 = \mu_3$, where the μ_j ’s denote population means. The F statistic for testing the hypothesis is

$$F = \frac{SSBG/(p - 1)}{SSWG/[p(n - 1)]} = \frac{MSBG}{MSWG}. \quad (2)$$

The numerator of this statistic estimates error effects (error variation) plus any effects attributable to the treatment. The denominator provides an independent

		Treat. level	
Group ₁	Participant ₁	a_1	$\bar{Y}_{\cdot 1}$
	Participant ₂	a_1	
	$\vdots$	$\vdots$	
	Participant ₁₅	a_1	
Group ₂	Participant ₁₆	a_2	$\bar{Y}_{\cdot 2}$
	Participant ₁₇	a_2	
	$\vdots$	$\vdots$	
	Participant ₃₀	a_2	
Group ₃	Participant ₃₁	a_3	$\bar{Y}_{\cdot 3}$
	Participant ₃₂	a_3	
	$\vdots$	$\vdots$	
	Participant ₄₅	a_3	

Figure 1 Layout for a completely randomized design (CR-3 design) where 45 participants were randomly assigned to three levels of treatment A with the restriction that 15 participants were assigned to each level. The dependent-variable means for participants in treatment levels a_1 , a_2 , and a_3 are denoted by $\bar{Y}_{\cdot 1}$, $\bar{Y}_{\cdot 2}$, and $\bar{Y}_{\cdot 3}$, respectively

estimate of error effects. Hence, the F statistic can be thought of as the ratio of error and treatment effects:

$$F = \frac{f(\text{error effects}) + f(\text{treatment effects})}{f(\text{error effects})}. \quad (3)$$

A large F statistic suggests that the dependent-variable population means or treatment effects are not all equal. An F statistic close to one suggests that there are no or negligible differences among the population means.

The advantages of a CR- p design are (a) simplicity in the randomization and statistical analysis and (b) flexibility with respect to having an equal or unequal number of participants in the treatment levels. A disadvantage is that differences among participants are controlled by random assignment. For this control to be effective, the participants should be relatively homogeneous or a relatively large number of participants should be used. The design described next, a **randomized block design**, enables a researcher to isolate and remove one source of variation among participants that ordinarily would be included in the estimate of the error effects. As a result, the randomized block design is usually more powerful than the completely randomized design.

Randomized Block Design

The *randomized block design*, denoted by RB- p , is appropriate for experiments that have one treatment with $p \geq 2$ treatment levels and n blocks. A block can contain a single participant who is observed under all p treatment levels or p participants who are similar with respect to a variable that is positively correlated with the dependent variable. If each block contains one participant, the order in which the treatment levels are administered is randomized independently for each block, assuming that the nature of the treatment permits this. If a block contains p matched participants, the participants in each block are randomly assigned to the treatment levels.

Consider the cigarette example again. It is reasonable to expect that the longer one has smoked, the more difficult it is to break the habit. Length of smoking is a **nuisance variable**, an undesired source of variation that can affect the dependent variable and contribute to the estimate of error effects. Suppose that the 45 smokers in the experiment are ranked in terms of the length of time they have smoked. The three smokers who have smoked for the shortest length of time are assigned to block 1, the next three smokers are assigned to block 2, and so on for the 15 blocks. Smokers in each block are similar with respect to length of time they have smoked. Differences among the 15 blocks reflect the effects of length of smoking. The layout for this design is shown in Figure 2. The total sum of squares and total degrees of freedom for the design are partitioned as follows:

$$SSTOTAL = SSA + SSBLOCKS$$

$$+ SSRESIDUAL$$

$$np - 1 = (p - 1) + (n - 1) + (n - 1)(p - 1), \quad (4)$$

where SSA denotes the treatment sum of squares and $SSBLOCKS$ denotes the block sum of squares. The $SSRESIDUAL$ is the interaction between the treatment and blocks; it is used to estimate error effects. Two null hypotheses can be tested.

$$H_0: \mu_{\cdot 1} = \mu_{\cdot 2} = \mu_{\cdot 3}$$

(treatment A population means are equal)

$$H_0: \mu_{1\cdot} = \mu_{2\cdot} = \dots = \mu_{15\cdot}$$

(block population means are equal) (5)

	Treat. level	Treat. level	Treat. level	
Block ₁	a_1	a_2	a_3	$\bar{Y}_{1\cdot}$
Block ₂	a_1	a_2	a_3	$\bar{Y}_{2\cdot}$
Block ₃	a_1	a_2	a_3	$\bar{Y}_{3\cdot}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
Block ₁₅	a_1	a_2	a_3	$\bar{Y}_{15\cdot}$
	$\bar{Y}_{\cdot 1}$	$\bar{Y}_{\cdot 2}$	$\bar{Y}_{\cdot 3}$	

Figure 2 Layout for a randomized block design (RB-3 design) where each block contains three matched participants who have smoked for about the same length of time. The participants in each block were randomly assigned to the three treatment levels. The mean cigarette consumption for participants in treatment levels a_1 , a_2 , and a_3 is denoted by $\bar{Y}_{\cdot 1}$, $\bar{Y}_{\cdot 2}$, and $\bar{Y}_{\cdot 3}$, respectively; the mean cigarette consumption for participants in Block₁, Block₂, ..., Block₁₅ is denoted by $\bar{Y}_{1\cdot}$, $\bar{Y}_{2\cdot}$, ..., $\bar{Y}_{15\cdot}$, respectively

The F statistics are

$$F = \frac{SSA/(p-1)}{SSRES/[(n-1)(p-1)]} = \frac{MSA}{MSRES}$$

and

$$F = \frac{SSBL/(n-1)}{SSRES/[(n-1)(p-1)]} = \frac{MSBL}{MSRES}. \quad (6)$$

The test of the block null hypothesis is of little interest because the blocks represent the nuisance variable of length of smoking.

The advantages of this design are (a) simplicity in the statistical analysis, and (b) the ability to isolate a nuisance variable so as to obtain greater power to reject a false null hypothesis. Disadvantages of the design include (a) the difficulty of forming homogeneous block or observing participants p times when p is large, and (b) the restrictive assumptions (sphericity and additive model) of the design. For a description of these assumptions, see Kirk [10, pp. 271–282].

Latin Square Design

The last building block design to be described is the Latin square design, denoted by LS- p . The design gets its name from an ancient puzzle that was concerned with the number of ways that Latin letters could be arranged in a square matrix so that each letter appeared once in each row and once

	c_1	c_2	c_3
b_1	a_1	a_2	a_3
b_2	a_2	a_3	a_1
b_3	a_3	a_1	a_2

Figure 3 Three-by-three Latin square where a_j denotes one of the $j = 1, \dots, p$ levels of treatment A , b_k denotes one of the $k = 1, \dots, p$ levels of nuisance variable B , and c_l denotes one of the $l = 1, \dots, p$ levels of nuisance variable C . Each level of treatment A appears once in each row and once in each column

in each column. A 3×3 Latin square is shown in Figure 3. The randomized block design enables a researcher to isolate one nuisance variable (variation among blocks) while evaluating the treatment effects. A Latin square design extends this procedure to two nuisance variables: variation associated with the rows of the square and variation associated with the columns of the square. As a result, the Latin square design is generally more powerful than the randomized block design.

In the cigarette smoking experiment, the nuisance variable of length of time that participants have smoked could be assigned to the rows of the square: b_1 = less than a year, b_2 = 1–3 years, and b_3 = more than three years. A second nuisance variable, number of cigarettes smoked per day, could be assigned to the columns of the square: c_1 = less than one pack, c_2 = 1–2 packs, and c_3 = more than two packs. The layout for this design is shown in Figure 4 and is based on the $a_j b_k c_l$ combinations in Figure 3. Five smokers who fit each of the $a_j b_k c_l$ combinations are randomly sampled from a large population of smokers who want to break the habit. The total sum of squares and total degrees of freedom are partitioned as follows:

$$SSTOTAL = SSA + SSB + SSC + SSRESIDUAL + SSWCELL$$

$$np^2 - 1 = (p-1) + (p-1) + (p-1) + (p-1)(p-2) + p^2(n-1), \quad (7)$$

where SSA denotes the treatment sum of squares, SSB denotes the row sum of squares, and SSC denotes the column sum of squares. $SSWCELL$ denotes the within cell sum of squares and estimates error effects. Three

Figure 4 Layout for a Latin square design (LS-3 design) that is based on the Latin square in Figure 3. Treatment A represents three kinds of therapy, nuisance variable B represents length of time that a person has smoked, and nuisance variable C represents number of cigarettes smoked per day. Participants in Group₁, for example, received behavioral therapy (a_1), had smoked for less than one year (b_1), and smoked less than one pack of cigarettes per day (c_1). The mean cigarette consumption for the participants in the nine groups is denoted by $\bar{Y}_{\cdot 111}, \bar{Y}_{\cdot 123}, \dots, \bar{Y}_{\cdot 331}$

null hypotheses can be tested.

$$\begin{aligned}
 H_0: \mu_{1..} &= \mu_{2..} = \mu_{3..} \\
 &\text{(treatment } A \text{ population means are equal)} \\
 H_0: \mu_{\cdot 1.} &= \mu_{\cdot 2.} = \mu_{\cdot 3.} \\
 &\text{(row population means are equal)} \\
 H_0: \mu_{\cdot \cdot 1} &= \mu_{\cdot \cdot 2} = \mu_{\cdot \cdot 3} \\
 &\text{(columns population means are equal)} \quad (8)
 \end{aligned}$$

The F statistics are

$$\begin{aligned}
 F &= \frac{SSA/(p-1)}{SSWCELL/[p^2(n-1)]} = \frac{MSA}{MSWCELL} \\
 F &= \frac{SSB/(p-1)}{SSWCELL/[p^2(n-1)]} = \frac{MSB}{MSWCELL} \\
 F &= \frac{SSC/(p-1)}{SSWCELL/[p^2(n-1)]} = \frac{MSC}{MSWCELL}. \quad (9)
 \end{aligned}$$

The advantage of the Latin square design is the ability to isolate two nuisance variables to obtain greater power to reject a false null hypothesis. The disadvantages are (a) the number of treatment levels, rows, and columns must be equal, a balance that may be difficult to achieve; (b) if there are any interactions among the treatment levels, rows, and columns, the test of the treatment is positively biased; and (c) the randomization is relatively complex.

Three building block designs have been described that provide the organizational framework for the classification scheme and nomenclature in this article. The following ANOVA designs are extensions of or variations of one of the building block designs or a combination of two or more building block designs.

Generalized Randomized Block Design

A *generalized randomized block design*, denoted by GRB- p , is a variation of a randomized block design. Instead of having n blocks of homogeneous participants, the GRB- p design has w groups of homogeneous participants. The $z = 1, \dots, w$ groups, like the blocks in a randomized block design, represent a nuisance variable. The GRB- p design is appropriate for experiments that have one treatment with $p \geq 2$ treatment levels and w groups each containing np homogeneous participants. The total number of participants in the design is $N = npw$. The np participants in each group are randomly assigned to the p treatment levels with the restriction that n participants are assigned to each level. The layout for the design is shown in Figure 5.

In the smoking experiment, suppose that 30 smokers are available to participate. The 30 smokers are ranked with respect to the length of time that they have smoked. The $np = (2)(3) = 6$ smokers who have smoked for the shortest length of time are assigned to group 1, the next six smokers are assigned to group 2, and so on. The six smokers in each group are then randomly assigned to the three treatment levels with the restriction that $n = 2$ smokers are assigned to each level.

The total sum of squares and total degrees of freedom are partitioned as follows:

		Treat. level		Treat. level		Treat. level
Group ₁	Participant ₁	a_1	Participant ₃	a_2	Participant ₅	a_3
	Participant ₂	a_1	Participant ₄	a_2	Participant ₆	a_3
Group ₂	Participant ₇	a_1	Participant ₉	a_2	Participant ₁₁	a_3
	Participant ₈	a_1	Participant ₁₀	a_2	Participant ₁₂	a_3
Group ₃	Participant ₁₃	a_1	Participant ₁₅	a_2	Participant ₁₇	a_3
	Participant ₁₄	a_1	Participant ₁₆	a_2	Participant ₁₈	a_3
Group ₄	Participant ₁₉	a_1	Participant ₂₁	a_2	Participant ₂₃	a_3
	Participant ₂₀	a_1	Participant ₂₂	a_2	Participant ₂₄	a_3
Group ₅	Participant ₂₅	a_1	Participant ₂₇	a_2	Participant ₂₉	a_3
	Participant ₂₆	a_1	Participant ₂₈	a_2	Participant ₃₀	a_3

Figure 5 Generalized randomized block design (GRB-3 design) with $p = 3$ treatment levels and $w = 5$ groups of $np = (2)(3) = 6$ homogeneous participants. The six participants in each group were randomly assigned to the three treatment levels with the restriction that two participants were assigned to each level

$$\begin{aligned}
 SSTOTAL &= SSA + SSG + SSA \times G \\
 &\quad + SSWCELL \\
 npw - 1 &= (p - 1) + (w - 1) + (p - 1)(w - 1) \\
 &\quad + pw(n - 1), \quad (10)
 \end{aligned}$$

where SSG denotes the groups sum of squares and $SSA \times G$ denotes the interaction of treatment A and groups. The within cells sum of squares, $SSWCELL$, is used to estimate error effects. Three null hypotheses can be tested.

$$\begin{aligned}
 H_0: \mu_1. &= \mu_2. = \mu_3. \\
 &\text{(treatment } A \text{ population means are equal)} \\
 H_0: \mu_{.1} &= \mu_{.2} = \dots = \mu_{.5} \\
 &\text{(group population means are equal)} \\
 H_0: \mu_{jz} - \mu_{j'z} - \mu_{jz'} + \mu_{j'z'} &= 0 \text{ for all } j, j', z, \\
 &\text{and } z' \text{ (treatment } A \text{ and groups do not interact)} \quad (11)
 \end{aligned}$$

The F statistics are

$$\begin{aligned}
 F &= \frac{SSA/(p - 1)}{SSWCELL/[pw(n - 1)]} = \frac{MSA}{MSWCELL} \\
 F &= \frac{SSG/(w - 1)}{SSWCELL/[pw(n - 1)]} = \frac{MSG}{MSWCELL}
 \end{aligned}$$

$$F = \frac{SSA \times G/(p - 1)(w - 1)}{SSWCELL/[pw(n - 1)]} = \frac{MSA \times G}{MSWCELL}. \quad (12)$$

The generalized randomized block design enables a researcher to isolate a nuisance variable—an advantage that it shares with the randomized block design. Furthermore, for the fixed-effects model, the design uses the pooled variation in the pw cells to estimate error effects rather than an interaction as in the randomized block design. Hence, the restrictive sphericity assumption of the randomized block design is replaced with the assumption of homogeneity of within cell population variances.

Graeco-Latin Square and Hyper-Graeco-Latin Square Designs

A *Graeco-Latin square design*, denoted by GLS- p , is constructed by superimposing one Latin square on a second Latin square that is orthogonal to the first. Two Latin squares are orthogonal if when they are superimposed, every treatment level of one square occurs once with every treatment level of the other square. An example of a 3×3 Graeco-Latin square is shown in Figure 6. The layout for a GLS-3 design with $n = 5$ participants in each cell is shown in Figure 7. The design is based on

	c_1	c_2	c_3
b_1	a_1d_1	a_2d_2	a_3d_3
b_2	a_2d_3	a_3d_1	a_1d_2
b_3	a_3d_2	a_1d_3	a_2d_1

Figure 6 Three-by-three Graeco-Latin square, where a_j denotes one of the $j = 1, \dots, p$ levels of treatment A , b_k denotes one of the $k = 1, \dots, p$ levels of nuisance variable B , c_l denotes one of the $l = 1, \dots, p$ levels of nuisance variable C , and d_m denotes one of the $m = 1, \dots, p$ levels of nuisance variable D . Each level of treatment A and nuisance variable D appear once in each row and once in each column and each level of A occurs once with each level of D

	Participant ₄₅	$a_3b_3c_1d_2$	

Figure 7 Layout for a 3×3 Graeco-Latin square design (GLS-3 design) that is based on the Graeco-Latin square in Figure 6

the $a_jb_kc_ld_m$ combinations in Figure 6. A Graeco-Latin square design enables a researcher to isolate three nuisance variables. However, the design is rarely used in the behavioral and social sciences for several reasons. First, the design is restricted to research problems in which three nuisance variables and a treatment each have the same number of levels. It is difficult to achieve this balance for four variables. Second, if interactions among the variables occur, one or more tests will be positively biased.

The prevalence of interactions in behavioral research limits the usefulness of the design.

A *hyper-Graeco-Latin square design*, denoted by HGLS- p , is constructed like a Graeco-Latin square design, but combines more than two orthogonal Latin squares. It shares the advantages and disadvantages of the Latin square and Graeco-Latin square designs.

Cross-over Design

A **cross-over design**, denoted by CO- p , is so called because participants are administered first one treatment level and then ‘crossed over’ to receive a second, and perhaps a third or even a fourth treatment level. The crossover design is appropriate for experiments having one treatment with $p \geq 2$ levels and two nuisance variables. One of the nuisance variables is blocks of participants (experimental units); the other nuisance variable is periods of time and must have p levels. Each treatment level must occur an equal number of times in each time period. Hence, the design requires $n = hp$ blocks, where h is a positive integer.

The simplest cross-over design has two treatment levels, a_1 and a_2 . Half of the participants receive a_1 followed by a_2 ; the other half receive a_2 followed by a_1 . The design can be used when it is reasonable to assume that participants revert to their original state before the second treatment level is administered. For example, the effects of a drug should be eliminated before a second drug is administered. **Carry-over effects**—treatment effects that continue after a treatment has been discontinued—are a potential threat to the **internal validity** of the design. Sometimes carry-over effects can be eliminated or at least minimized by inserting a rest or washout period between administrations of the treatment levels. Alternatively, a complex cross-over design can be used that provides a statistical adjustment for the carry-over effects of the immediately preceding treatment level. These designs are discussed by Cochran and Cox [3], Federer [5], and Jones and Kenward [8].

Cross-over designs have features of randomized block and Latin square designs. For example, each participant receives all p treatment levels and serves as his or her own control, as in a randomized block design with repeated measures (see **Repeated Measures Analysis of Variance**).

And, as in a Latin square design, each treatment level occurs an equal number of times in each time period, and the effects of two nuisance variables—blocks and time periods—can be isolated. Cross-over designs are often used in clinical trials, agricultural research, and marketing research. The layout for a CO-2 design with eight blocks is shown in Figure 8.

The total sum of squares and total degrees of freedom for the design are partitioned as follows:

$$\begin{aligned} SSTOTAL &= SSA + SSTP + SSBLOCKS \\ &\quad + SSRESIDUAL \\ np - 1 &= (p - 1) + (p - 1) + (n - 1) \\ &\quad + (n - 2)(p - 1), \end{aligned} \quad (13)$$

where $SSTP$ denotes the time-periods sum of squares. Three null hypotheses can be tested.

$$\begin{aligned} H_0: \mu_{.1.} &= \mu_{.2.} \\ &\text{(treatment A population means are equal)} \\ H_0: \mu_{..1} &= \mu_{..2} \\ &\text{(time-periods population means are equal)} \\ H_0: \mu_{1..} &= \mu_{2..} = \cdots = \mu_{8..} \\ &\text{(block population means are equal)} \end{aligned} \quad (14)$$

	Time period b_1	Time period b_2
	Treat. level	Treat. level
Block ₁	a_1	a_2
Block ₂	a_2	a_1
Block ₃	a_2	a_1
Block ₄	a_1	a_2
Block ₅	a_2	a_1
Block ₆	a_1	a_2
Block ₇	a_2	a_1
Block ₈	a_1	a_2

Figure 8 Layout for a cross-over design with two treatment levels and two time periods (CO-2 design). Each block contains $p = 2$ treatment levels, and each treatment level occurs an equal number of times in each time period. The participants were randomly assigned to the blocks

The F statistics are

$$\begin{aligned} F &= \frac{SSA/(p - 1)}{SSRESIDUAL/[(n - 2)(p - 1)]} \\ &= \frac{MSA}{MSRESIDUAL} \\ F &= \frac{SSTP/(p - 1)}{SSRESIDUAL/[(n - 2)(p - 1)]} \\ &= \frac{MSTP}{MSRESIDUAL} \\ F &= \frac{SSBLOCKS/(n - 1)}{SSRESIDUAL/[(n - 2)(p - 1)]} \\ &= \frac{MSBLOCKS}{MSRESIDUAL}. \end{aligned} \quad (15)$$

The design shares the advantages and limitations of the randomized block and Latin square designs. In particular, it must be reasonable to assume that there are no interactions among the blocks, time periods, and treatment. If this assumption is not satisfied, a test of one or more of the corresponding effects is biased. Finally, statistical adjustments are required if carry-over effects of the immediately preceding treatment level are present.

Incomplete Block Designs

The name *incomplete block design* refers to a large class of designs in which p treatment levels of a single treatment are assigned to blocks of size k , where $k < p$. In many respects, the designs are similar to randomized block designs. However, incomplete block designs are typically used when a researcher wants to evaluate a large number of treatment levels. In such situations, the use of a randomized block design, an alternative design choice, may not be feasible because of the difficulty in observing participants over and over again or the difficulty in forming sufficiently homogeneous blocks.

The layout for a **balanced incomplete block design** with seven treatment levels, denoted by BIB-7, is shown in Figure 9. This design enables a researcher to evaluate seven treatment levels using blocks of size three. Each pair of treatment levels occurs in some block an equal number of times. Balanced incomplete block designs with many treatment levels, say $p > 10$, may require a prohibitively large number of blocks. For example, a BIB-10 design with

	Treat. level	Treat. level	Treat. level
Block ₁	a_1	a_2	a_4
Block ₂	a_2	a_3	a_5
Block ₃	a_3	a_4	a_6
Block ₄	a_4	a_5	a_7
Block ₅	a_5	a_6	a_1
Block ₆	a_6	a_7	a_2
Block ₇	a_7	a_1	a_3

Figure 9 Layout for a balanced incomplete block design with seven treatment levels in blocks of size three (BIB-7 design)

blocks of size three requires 30 blocks. A smaller number of blocks can be used if the design is partially balance, that is, each pair of treatment levels does not occur within some block an equal number of times. Such designs are called *partially balanced incomplete block designs* and are denoted by PBIB- p .

Another large group of incomplete block designs are *lattice designs*. Unlike the incomplete block designs just described, the layout and analysis of lattice designs are facilitated by establishing a correspondence between the p treatment levels of the design and the treatment combinations of a factorial design. Factorial designs are described later. Lattice designs can be balanced, denoted by LBIB- p , partially balanced, denoted by LPBIB- p , and unbalanced, denoted by LUBIB- p .

Yet another group of incomplete block designs is based on an incomplete Latin square. One example is the *Youden square design*, denoted by YBIB- p (see **Balanced Incomplete Block Designs**). The design combines features of balanced incomplete block designs and Latin square designs. A Youden square design is constructed by omitting one or more columns of a Latin square. Hence the design is not really a square. Consider the layout for a YBIB-4 design shown in Figure 10. A 4×4 Latin square is shown below the YBIB-4 design. An examination of the YBIB-4 design reveals that it contains the treatment levels in columns 1–3 of the Latin square.

Incomplete block designs are rarely used in the behavioral and social sciences for several reasons. First, the designs are most useful when the number of treatment levels, p , is very large. Researchers in the behavioral and social sciences seldom design experiments with $p > 7$. Second, researchers are often interested in simultaneously evaluating two or more

b_4	a_4	a_1	a_2	a_3

Figure 10 The top figure shows the layout for a Youden square design with four treatment levels in blocks of size three (YBIB-4 design). The design contains the treatment levels in columns c_1 , c_2 , and c_3 of the Latin square shown in the lower figure

treatments and associated interactions. All of the designs described so far are appropriate for experiments with one treatment. The designs described next can be used when a researcher is interested in simultaneously evaluating several treatments and associated interactions.

Completely Randomized Factorial Design

Factorial designs differ from those described previously in that two or more treatments can be evaluated simultaneously and, in addition, the **interaction** between the treatments can be evaluated. Each level of one treatment must occur once with each level of other treatments and vice versa, that is, the treatments must be crossed. Although there are many kinds of factorial design, they are all constructed by combining two or more building block designs.

The simplest factorial design from the standpoint of randomization procedures and data analysis is the *completely randomized factorial design*. The design is denoted by CRF- pq , where CR indicates the building block design and F indicates that it is a factorial design. The design is constructed by combining the levels of a CR- p design for treatment A with those of a second CR- q design for treatment B so that each level of the CR- p design appears once with each level of the CR- q design and vice versa. The levels of the two treatments, A and B , are said to be completely crossed.

Hence, the design has $p \times q$ treatment combinations, $a_1b_1, a_1b_2, \dots, a_pb_q$. The layout for a CRF-23 design with $p = 2$ levels of treatment A and $q = 3$ levels of treatment B is shown in Figure 11. In this example, 30 participants are randomly assigned to the $2 \times 3 = 6$ treatment combinations with the restriction that $n = 5$ participants are assigned to each combination.

The total sum of squares and total degrees of freedom for the design are partitioned as follows:

$$\begin{aligned} SSTOTAL &= SSA + SSB + SSA \times B \\ &\quad + SSWCELL \\ npq - 1 &= (p - 1) + (q - 1) + (p - 1)(q - 1) \\ &\quad + pq(n - 1), \end{aligned} \quad (16)$$

where $SSA \times B$ denotes the interaction of treatments A and B . Three null hypotheses can be tested.

$$H_0: \mu_{1\cdot} = \mu_{2\cdot}.$$

(treatment A population means are equal)

$$H_0: \mu_{\cdot 1} = \mu_{\cdot 2} = \mu_{\cdot 3}$$

(treatment B population means are equal)

$$H_0: \mu_{jk} - \mu_{j'k} - \mu_{jk'} + \mu_{j'k'} = 0 \text{ for all } j, j', k,$$

and k' (treatments A and B do not interact)

(17)

The F statistics are

$$\begin{aligned} F &= \frac{SSA/(p - 1)}{SSWCELL/[pq(n - 1)]} = \frac{MSA}{MSWCELL} \\ F &= \frac{SSB/(q - 1)}{SSWCELL/[pq(n - 1)]} = \frac{MSB}{MSWCELL} \\ F &= \frac{SSA \times B/(p - 1)(q - 1)}{SSWCELL/[pq(n - 1)]} = \frac{MSA \times B}{MSWCELL}. \end{aligned} \quad (18)$$

The advantages of the design are as follows: (a) All participants are used in simultaneously evaluating the effects of two or more treatments. The effects of each treatment are evaluated with the same precision as if the entire experiment had been devoted to that treatment alone. Thus, the design permits efficient use of resources. (b) The interactions among the treatments can be evaluated. The disadvantages of the design are as follows. (a) If numerous treatments are included in the experiment, the number of participants required can be prohibitive. (b) A factorial design lacks simplicity in the interpretation of results if interaction effects are present. Unfortunately, interactions among variables in the behavioral sciences and education are common. (c) The use of a factorial design commits a researcher to a relatively large experiment. Small exploratory experiments may indicate much more promising lines of investigation than those originally envisioned. Relatively small experiments permit greater freedom in the pursuit of serendipity.

Randomized Block Factorial Design

A two-treatment *randomized block factorial design* is denoted by RBF- pq . The design is constructed by combining the levels of an RB- p design with those of an RB- q design so that each level of the RB- p design appears once with each level of the RB- q design and vice versa. The design uses the blocking technique described in connection with a randomized block design to isolate variation attributable to a nuisance variable while simultaneously evaluating two or more treatments and associated interactions.

Figure 12 Layout for a two-treatment, randomized block factorial design (RBF-32 design)

An RBF-32 design has blocks of size $3 \times 2 = 6$. If a block consists of matched participants, n blocks of six matched participants must be formed. The participants in each block are randomly assigned to the $a_1b_1, a_1b_2, \dots, a_pb_q$ treatment combinations. Alternatively, if repeated measures are obtained, each participant must be observed six times. For this case, the order in which the treatment combinations are administered is randomized independently for each block, assuming that the nature of the treatments permits this. The layout for the design is shown in Figure 12.

The total sum of squares and total degrees of freedom for an RBF-32 design are partitioned as follows:

$$\begin{aligned}
 SSTOTAL &= SSA + SSB + SSA \times B \\
 &\quad + SSRESIDUAL \\
 npq - 1 &= (p - 1) + (q - 1) + (p - 1)(q - 1) \\
 &\quad + (n - 1)(pq - 1). \quad (19)
 \end{aligned}$$

Three null hypotheses can be tested.

$$\begin{aligned}
 H_0: \mu_{1.} &= \mu_{2.} = \mu_{3.} \\
 &\quad \text{(treatment } A \text{ population means are equal)} \\
 H_0: \mu_{.1} &= \mu_{.2} \\
 &\quad \text{(treatment } B \text{ population means are equal)} \\
 H_0: \mu_{jk} - \mu_{j'k} - \mu_{jk'} + \mu_{j'k'} &= 0 \text{ for all } j, j', k, \\
 &\quad \text{and } k' \text{ (treatments } A \text{ and } B \text{ do not interact)} \quad (20)
 \end{aligned}$$

The F statistics are

$$\begin{aligned}
 F &= \frac{SSA/(p - 1)}{SSRESIDUAL/[(n - 1)(pq - 1)]} \\
 &= \frac{MSA}{MSRESIDUAL}
 \end{aligned}$$

$$\begin{aligned}
 F &= \frac{SSB/(q - 1)}{SSRESIDUAL/[(n - 1)(pq - 1)]} \\
 &= \frac{MSB}{MSRESIDUAL} \\
 F &= \frac{SSA \times B/(p - 1)(q - 1)}{SSRESIDUAL/[(n - 1)(pq - 1)]} \\
 &= \frac{MSA \times B}{MSRESIDUAL}. \quad (21)
 \end{aligned}$$

The design shares the advantages and disadvantages of the randomized block design. It has an additional disadvantage: if treatment A or B has numerous levels, say four or five, the block size becomes prohibitively large. Designs that reduce the block size are described next.

Split-plot Factorial Design

The *split-plot factorial* design is appropriate for experiments with two or more treatments where the number of treatment combinations exceeds the desired block size. The term *split-plot* comes from agricultural experimentation where the levels of, say, treatment A are applied to relatively large plots of land—the whole plots. The whole plots are then split or subdivided and the levels of treatment B are applied to the subplots within each whole plot.

A two-treatment, split-plot factorial design is constructed by combining a CR- p design with an RB- q design. In the split-plot factorial design, the assignment of participants to treatment combinations is carried out in two stages. To illustrate, again consider the smoking example. Suppose that we are interested in comparing the three therapies and also in comparing two lengths of the therapy, $b_1 =$ three months and $b_2 =$ six months. If 60 smokers are available, they can be ranked in terms of the length of time that they

have smoked. The two participants who have smoked for the shortest time are assigned to one block, the next two smokers to another block, and so on. This procedure produces 30 blocks in which the two smokers in a block are similar in terms of the length of time they have smoked. In the first stage of randomization, the 30 blocks are randomly assigned to the three levels of treatment A with the restriction that 10 blocks are assigned to each level of treatment A . In the second stage of randomization, the two smokers in each block are randomly assigned to the two levels of treatment B with the restriction that b_1 and b_2 appear equally often in each level of treatment A . An exception to this randomization procedure must be made when treatment B is a temporal variable, such as successive learning trials or periods of time. Trial two, for example, cannot occur before trial one.

The layout for this split-plot factorial design with three levels of treatment A and two levels of treatment B is shown in Figure 13. The total sum of squares and total degrees of freedom are partitioned as follows:

$$\begin{aligned}
 SSTOTAL &= SSA + SSBL(A) + SSB + SSA \times B \\
 &\quad + SSRESIDUAL \\
 npq - 1 &= (p - 1) + p(n - 1) + (q - 1) \\
 &\quad + (p - 1)(q - 1) + p(n - 1)(q - 1),
 \end{aligned} \tag{22}$$

where $SSBL(A)$ denotes the sum of squares of blocks that are nested in the p levels of treatment

		Treat. comb. b_1	Treat. comb. b_2

		$\bar{Y}_{\cdot 1}$	$\bar{Y}_{\cdot 2}$	

Figure 13 Layout for a two-treatment, split-plot factorial design (SPF-3·2 design). Treatment A is confounded with groups

A . Three null hypotheses can be tested.

$$H_0: \mu_{\cdot 1 \cdot} = \mu_{\cdot 2 \cdot} = \mu_{\cdot 3 \cdot}$$

(treatment A population means are equal)

$$H_0: \mu_{\cdot \cdot 1} = \mu_{\cdot \cdot 2}$$

(treatment B population means are equal)

$$H_0: \mu_{\cdot jk} - \mu_{\cdot j'k} - \mu_{\cdot jk'} + \mu_{\cdot j'k'} = 0 \text{ for all } j, j', k, \text{ and } k' \text{ (treatments } A \text{ and } B \text{ do not interact) (23)}$$

The F statistics are

$$\begin{aligned}
 F &= \frac{SSA/(p - 1)}{SSBL(A)/[p(n - 1)]} \\
 &= \frac{MSA}{MSBL(A)} \\
 F &= \frac{SSB/(q - 1)}{SSRESIDUAL/[p(n - 1)(q - 1)]} \\
 &= \frac{MSB}{MSRESIDUAL} \\
 F &= \frac{SSA \times B/(p - 1)(q - 1)}{SSRESIDUAL/[p(n - 1)(q - 1)]} \\
 &= \frac{MSA \times B}{MSRESIDUAL}.
 \end{aligned} \tag{24}$$

Treatment A is called a *between-blocks effect*. The error term for testing between-blocks effects is $MSBL(A)$. Treatment B and the $A \times B$ interaction are *within-blocks effects*. The error term for testing the within-blocks effects is $MSRESIDUAL$. The designation for a two-treatment, split-plot factorial design is SPF- $p \cdot q$. The p preceding the dot denotes the number of levels of the between-blocks treatment; the q after the dot denotes the number of levels of the within-blocks treatment. Hence, the design in Figure 13 is an SPF-3·2 design. A careful examination of the randomization and layout of the between-blocks effects reveals that they resemble those for a CR-3 design. The randomization and layout of the within-blocks effects at each level of treatment A resemble those for an RB-2 design.

The block size of the SPF-3·2 design in Figure 13 is three. The RBF-32 design in Figure 12 contains the same $3 \times 2 = 6$ treatment combinations, but the block size is six. The advantage of the split-plot factorial – the smaller block size – is achieved by confounding groups of blocks with treatment A . Consider the sample means $\bar{Y}_{\cdot 1}$, $\bar{Y}_{\cdot 2}$, and $\bar{Y}_{\cdot 3}$ in

Figure 13. The differences among the means reflect the differences among the three groups of smokers as well as the differences among the three levels of treatment A. To put it another way, we cannot tell how much of the differences among the three sample means is attributable to the differences among Group₁, Group₂, and Group₃, and how much is attributable to the differences among treatments levels a_1 , a_2 , and a_3 . For this reason, the groups and treatment A are said to be *completely confounded* (see **Confounding Variable**).

The use of confounding to reduce the block size in an SPF- $p \cdot q$ design involves a trade-off that needs to be made explicit. The RBF-32 design uses the same error term, *MSRESIDUAL*, to test hypotheses for treatments A and B and the $A \times B$ interaction. The two-treatment, split-plot factorial design, however, uses two error terms: *MSBL(A)* is used to test treatment A; a different and usually much smaller error term, *MSRESIDUAL*, is used to test treatment B and the $A \times B$ interaction. As a result, the **power** of the tests of treatment B and the $A \times B$ interaction is greater than that for treatment A. Hence, a split-plot factorial design is a good design choice if a researcher is more interested in treatment B and the $A \times B$ interaction than in treatment A. When both treatments and the $A \times B$ interaction are of equal interest, a randomized block factorial design is a better choice if the larger block size is acceptable. If a large block size is not acceptable and the researcher is primarily interested in treatments A and B, an alternative design choice is the confounded factorial design. This design, which is described next, achieves a reduction in block size by confounding groups of blocks with the $A \times B$ interaction. As a result, tests of treatments A and B are more powerful than the test of the $A \times B$ interaction.

Confounded Factorial Designs

Confounded factorial designs are constructed from either randomized block designs or Latin square designs. A simple confounded factorial design is denoted by RBCF- p^k . The RB in the designation indicates the building block design, C indicates that an interaction is completely confounded with groups, k indicates the number of treatments, and p indicates the number of levels of each treatment. The layout for an RBCF-2² design is shown in Figure 14. The

		Treat. comb.	Treat. comb.

	$\vdots$	$\vdots$	$\vdots$	
	Block _{$2n$}	a_1b_2	a_2b_1	

Figure 14 Layout for a two-treatment, randomized block confounded factorial design (RBCF-2² design). The $A \times B$ interaction is confounded with groups

total sum of squares and total degrees of freedom are partitioned as follows:

$$\begin{aligned}
 SSTOTAL &= SSA \times B + SSBL(G) + SSA + SSB \\
 &\quad + SSRESIDUAL \\
 nvw - 1 &= (w - 1) + w(n - 1) + (p - 1) + (q - 1) \\
 &\quad + w(n - 1)(v - 1), \quad (25)
 \end{aligned}$$

where *SSBL(G)* denotes the sum of squares of blocks that are nested in the w groups and v denotes the number of combinations of treatments A and B in each block. Three null hypotheses can be tested.

$$H_0: \mu_{\cdot jk} - \mu_{\cdot j'k} - \mu_{\cdot jk'} + \mu_{\cdot j'k'} = 0 \text{ for all } j,$$

$$j', k, \text{ and } k' \text{ (treatments A and B do not interact)}$$

$$H_0: \mu_{\cdot 1\cdot} = \mu_{\cdot 2\cdot}$$

$$\text{(treatment A population means are equal)}$$

$$H_0: \mu_{\cdot 1\cdot} = \mu_{\cdot 2\cdot}$$

$$\text{(treatment B population means are equal)} \quad (26)$$

The F statistics are

$$\begin{aligned}
 F &= \frac{SSA \times B / (w - 1)}{SSBL(G) / [w(n - 1)]} \\
 &= \frac{MSA \times B}{MSBL(G)} \\
 F &= \frac{SSA / (p - 1)}{SSRESIDUAL / [w(n - 1)(v - 1)]} \\
 &= \frac{MSA}{MSRESIDUAL} \\
 F &= \frac{SSB / (q - 1)}{SSRESIDUAL / [w(n - 1)(v - 1)]}
 \end{aligned}$$

$$= \frac{MSB}{MSRESIDUAL}. \quad (27)$$

In this example, groups are confounded with the $A \times B$ interaction. Hence, a test of the interaction is also a test of differences among the groups and vice versa.

A randomized block factorial design with two levels of treatments A and B has blocks of size four. The RBCF- 2^2 design confounds the $A \times B$ interaction with groups and thereby reduces the block size to two. The power of the tests of the two treatments is usually much greater than the power of the test of the $A \times B$ interaction. Hence, the RBCF- 2^2 design is a good design choice if a small block size is required and the researcher is primarily interested in the tests of the treatments.

For experiments with three treatments, A , B , and C , each having p levels, a researcher can confound one interaction, say $A \times B \times C$, with groups and not confound the treatments or two-treatment interactions. The design is called a *partially confounded factorial design* and is denoted by RBPF- p^3 , where P indicates partial confounding. A two-treatment, confounded factorial design that is based on a Latin square is denoted by LSCF- p^2 .

Two kinds of confounding have been described: group-treatment confounding in an SPF- $p \cdot q$ design and group-interaction confounding in RBCF- p^k and LSCF- p^k designs. A third kind of confounding, treatment-interaction confounding, is described next.

Fractional Factorial Design

Confounded factorial designs reduce the number of treatment combinations that appear in a block. Fractional factorial designs use treatment-interaction confounding to reduce the number of treatment combinations that appear in an experiment. For example, the number of treatment combinations that must be included in a multitreatment experiment can be reduced to some fraction—1/2, 1/3, 1/4, 1/8, 1/9, and so on—of the total number of treatment combinations in an unconfounded factorial design.

Fractional factorial designs are constructed using completely randomized, randomized block, and Latin square building block designs. The resulting designs are denoted by CRFF- $p^k - i$, RBFF- $p^k - i$, and LSFF- p^k , respectively, where CR, RB, and LS denote the building block design. The letters FF in the

acronyms indicate a fractional factorial design, k indicates the number of treatments, p indicates the number of levels of each treatment, and i indicates the fraction of the treatment combinations in the design. For example, if $k = 2$ and $i = 1$, the design contains 1/2 of the combinations of a complete factorial design; if $i = 2$, the design contains 1/4 of the combinations.

To conserve space, I show the layout in Figure 15 for a very small CRFF- 2^{3-1} design with three treatments. Ordinarily, a fractional factorial design would have many more treatments. The total sum of squares and degrees of freedom are partitioned as follows:

$$\begin{aligned} SSTOTAL &= SSA[B \times C] + SSB[A \times C] \\ &\quad + SSC[A \times B] + SSWCELL \\ npq - 1 &= (p - 1) + (q - 1) + (r - 1) \\ &\quad + pq(n - 1), \end{aligned} \quad (28)$$

where $SSA[B \times C]$, for example, denotes the sum of squares for treatment A that is indistinguishable from the $B \times C$ interaction. Treatment A and the $B \times C$ interaction are two labels for the same source of variation—they are *aliases*. Notice that the total sum of squares does not include the $A \times B \times C$ interaction. Three null hypotheses can be tested.

$$H_0: \mu_{1..} = \mu_{2..}$$

		Treat. comb.

Group ₂	Participant _{$n+1$}	$a_1b_2c_2$	$\bar{Y}_{.122}$
	Participant _{$2n$}	$a_1b_2c_2$	
Group ₃	Participant _{$2n+1$}	$a_2b_1c_2$	$\bar{Y}_{.212}$
	Participant _{$3n$}	$a_2b_1c_2$	
Group ₄	Participant _{$3n+1$}	$a_2b_2c_1$	$\bar{Y}_{.221}$
	Participant _{$4n$}	$a_2b_2c_1$	

Figure 15 Layout for a three-treatment, fractional factorial design (CRFF- 2^{3-1}). A three-treatment, completely randomized factorial design with two levels of each treatment (CRF- 2^3 design) would have $2 \times 2 \times 2 = 8$ treatment combinations. The fractional factorial design contains only $1/2(8) = 4$ of the combinations

(treatment A population means are equal
or the $B \times C$ interaction is zero)

$$H_0: \mu_{.1.} = \mu_{.2.}$$

(treatment B population means are equal
or the $A \times C$ interaction is zero)

$$H_0: \mu_{..1} = \mu_{..2}$$

(treatment C population means are equal
or the $A \times B$ interaction is zero) (29)

The F statistics are

$$\begin{aligned} F &= \frac{SSA/(p-1)}{SSWCELL/pq(n-1)} = \frac{MSA}{MSWCELL} \\ F &= \frac{SSB/(q-1)}{SSWCELL/pq(n-1)} = \frac{MSB}{MSWCELL} \\ F &= \frac{SSC/(r-1)}{SSWCELL/pq(n-1)} = \frac{MSC}{MSWCELL}. \end{aligned} \quad (30)$$

In this example, treatments are aliased with interactions. Hence, if $F = MSA/MSWCELL$ is significant, a researcher does not know whether it is because treatment A is significant, or because the $B \times C$ interaction is significant, or both.

You may wonder why anyone would use such a design—after all, experiments are supposed to help us resolve ambiguity not create it. Fractional factorial designs are typically used in exploratory research situations where a researcher is interested in six or more treatments and can perform follow-up experiments if necessary. Suppose that a researcher wants to perform an experiment with six treatments each having two levels. A CRF-222222 design would have $2 \times 2 \times 2 \times 2 \times 2 \times 2 = 64$ treatment combinations. If two participants are randomly assigned to each combination, a total of $2 \times 64 = 128$ participants would be required. By using a one-fourth fractional factorial design, CRFF- 2^{6-2} design, the researcher can reduce the number of treatment combinations in the experiment from 64 to 16 and the number of participants from 128 to 32. If none of the F statistics are significant, the researcher has answered the research questions with one-fourth of the effort. If, however, some of the F statistics are significant, the researcher can perform several small follow-up experiments to determine what is significant.

In summary, the main advantage of a fractional factorial design is that it enables a researcher to efficiently investigate a large number of treatments in an initial experiment, with subsequent experiments designed to focus on the most promising lines of investigation or to clarify the interpretation of the original analysis. Many researchers would consider ambiguity in interpreting the outcome of the initial experiment a small price to pay for the reduction in experimental effort.

Hierarchical Designs

The multitreatment designs that have been discussed have had crossed treatments. Treatments A and B are crossed if each level of treatment B appears once with each level of treatment A and visa versa. Treatment B is *nested* in treatment A if each level of treatment B appears with only one level of treatment A . The nesting of treatment B in treatment A is denoted by $B(A)$ and is read, ‘ B within A ’. A hierarchical design (see **Hierarchical Models**) has at least one nested treatment; the remaining treatments are either nested or crossed.

Hierarchical designs are constructed from two or more or a combination of completely randomized and randomized block designs. A two-treatment, hierarchical design that is constructed from two completely randomized designs is denoted by CRH- $pq(A)$, where H indicates a hierarchical design and $pq(A)$ indicates that the design has p levels of treatment A and q levels of treatment $B(A)$ that are nested in treatment A . A comparison of nested and crossed treatments is shown in Figure 16.

Experiments with one or more nested treatments are well suited to research in education, industry, and the behavioral and medical sciences. Consider an example from the medical sciences. A researcher wants to compare the efficacy of a new drug, denoted

Figure 16 Figure (a) illustrates crossed treatments. In Figure (b), treatment $B(A)$ is nested in treatment A

by a_1 , with the currently used drug, denoted by a_2 . Four hospitals denoted by $b_1, \dots, b_4$, which is treatment $B(A)$, are available to participate in the experiment. Because expensive equipment is needed to monitor the side effects of the new drug, the researcher decided to use the new drug in two of the four hospitals and the current drug in the other two hospitals. The drugs are randomly assigned to the hospitals with the restriction that each drug is assigned to two hospitals. N patients are randomly assigned to the four drug-hospital combinations with the restriction that n patients are assigned to each combination. Figure 16 (b), shown earlier, illustrates the nesting of treatment $B(A)$ in treatment A . The layout for this CRH-24(A) design with two levels of treatment A and four levels of treatment $B(A)$ is shown in Figure 17.

The total sum of squares and total degrees of freedom for the CRH-24(A) design are partitioned as follows:

$$SSTOTAL = SSA + SSB(A) + SSWCELL$$

$$npq_{(j)} - 1 = (p - 1) + p(q_{(j)} - 1) + pq_{(j)}(n - 1), \quad (31)$$

where $q_{(j)}$ is the number of levels of treatment $B(A)$ that is nested in the j th level of treatment A . The design enables a researcher to test two null

hypotheses.

$$H_0: \mu_{1\cdot} = \mu_{2\cdot}$$

(treatment A population means are equal)

$$H_0: \mu_{11} = \mu_{12} \text{ or } \mu_{23} = \mu_{24}$$

(treatment $B(A)$ population means are equal)

(32)

If the second null hypothesis is rejected, the researcher can conclude that the dependent variable is not the same for the populations represented by hospitals b_1 and b_2 , or the dependent variable is not the same for the populations represented by hospitals b_3 and b_4 , or both. However, the test of treatment $B(A)$ does not address the question of whether $\mu_{11} = \mu_{23}$, for example, because hospitals b_1 and b_3 were assigned to different levels of treatment A . Also, because treatment $B(A)$ is nested in treatment A , it is not possible to test the $A \times B$ interaction. The F statistics are

$$F = \frac{SSA/(p - 1)}{SSWCELL/[pq_{(j)}(n - 1)]} = \frac{MSA}{MSWCELL}$$

$$F = \frac{SSB(A)/p(q_{(j)} - 1)}{SSWCELL/[pq_{(j)}(n - 1)]} = \frac{MSB(A)}{MSWCELL}. \quad (33)$$

Figure 17 Layout for a two-treatment, completely randomized hierarchical design, CRH-24(A) design, in which treatment $B(A)$ is nested in treatment A . The twenty participants were randomly assigned to four combinations of treatments A and $B(A)$ with the restriction that five participants were assigned to each treatment combination

As is often the case, the nested treatment in the drug example resembles a nuisance variable. The researcher probably would not conduct the experiment just to find out whether the dependent variable is different for the two hospitals assigned to drug a_1 or the two hospitals assigned to drug a_2 . The important question is whether the new drug is more effective than the currently used drug.

Hierarchical designs with three or more treatments can have both nested and crossed treatments. If at least one treatment is nested and two or more treatments are crossed, the design is a partial hierarchical design. For example, treatment $B(A)$ can be nested in treatment A and treatment C can be crossed with both treatments A and $B(A)$. This design is denoted by CRPH- $pq(A)r$, where PH indicates a partial hierarchical design. The nesting configuration for this design is shown in Figure 18.

Lack of space prevents me from describing other partial hierarchical designs with different combinations of crossed and nested treatments. The interested

Figure 18 Nesting configuration of the three treatments in a CRPH-24(A)2 design. The four levels of treatment $B(A)$ are nested in the two levels of treatment A ; the two levels of treatment C are crossed with treatments A and $B(A)$

reader is referred to the extensive treatment of these designs in Kirk [10].

Analysis of Covariance

The discussion so far has focused on designs that use *experimental control* to reduce error variance and minimize the effects of nuisance variables. Experimental control can take different forms such as random assignment of participants to treatment levels, stratification of participants into homogeneous blocks, and refinement of techniques for measuring a dependent variable. **Analysis of covariance**, ANCOVA, is an alternative approach to reducing error variance and minimizing the effects of nuisance variables. The approach combines regression analysis with ANOVA and involves measuring one or more *concomitant variables* (also called *covariates*) in addition to the dependent variable. The concomitant variable represents a source of variation that was not controlled in the experiment and a source that is believed to affect the dependent variable. When this approach is used, the letters AC are appended to the designation for a design, for example, CRFAC-*pq*.

ANCOVA enables a researcher to (1) remove that portion of the dependent-variable error variance that is predictable from a knowledge of the concomitant variable thereby increasing power and (2) adjust the dependent-variable means so that they are free of the linear effects attributable to the concomitant variable thereby reducing bias. ANCOVA is often used in three kinds of research situations. One situation involves the use of intact groups with unequal concomitant-variable means and is common in educational and industrial research. The procedure statistically equates the intact groups so that their concomitant-variable means are equal. Unfortunately,

a researcher can never be sure that the concomitant-variable means that are adjusted represent the only nuisance variable or the most important nuisance variable on which the intact groups differ. Random assignment is the best safeguard against unanticipated nuisance variables. In the long run, over many replications of an experiment, random assignment will result in groups that are, at the time of assignment, similar on all nuisance variables.

ANCOVA also can be used to adjust concomitant-variable means when it becomes apparent at some time that although participants were randomly assigned to the treatment levels, the participants in the different groups were not equivalent on a relevant nuisance variable at the beginning of the experiment. Finally, ANCOVA can be used to adjust concomitant-variable means for differences in a relevant nuisance variable that develops during an experiment.

Statistical control and experimental control are not mutually exclusive approaches to reducing error variance and minimizing the effects of nuisance variables. It may be convenient to control some variables by experimental control and others by statistical control. In general, experimental control involves fewer assumptions than statistical control. However, experimental control requires more information about the participants before beginning an experiment. Once data collection has begun, it is too late to randomly assign participants to treatment levels or to form blocks of dependent participants. The advantage of statistical control is that it can be used after data collection has begun. Its disadvantage is that it involves a number of assumptions such as a linear relationship between the dependent and concomitant variables and equal within-groups regression coefficients that may prove untenable in a particular experiment.

Summary of ANOVA Nomenclature and Acronyms

The nomenclature and acronyms for ANOVA designs are summarized in Table 1. The classification of designs in Table 1 is based on (a) the number of treatments, (b) whether participants are assigned to relatively homogeneous blocks prior to random assignment, (c) the building block design, (d) presence or absence of confounding, (e) use of crossed or nested treatments, and (f) use of a covariate. The nomenclature owes much to Cochran and Cox [3] and Federer [5].

Table 1 Classification of ANOVA designs

ANOVA design	Acronym
I Designs with One Treatment	
A Treatment levels randomly assigned to experimental units	
1. Completely randomized design	CR- p
B Experimental units assigned to relatively homogeneous blocks or groups prior to random assignment	
1. Balanced incomplete block design	BIB- p
2. Cross-over design	CO- p
3. Generalized randomized block design	GRB- p
4. Graeco-Latin square design	GLS- p
5. Hyper-Graeco-Latin square design	HGLS- p
6. Latin square design	LS- p
7. Lattice balanced incomplete block design	LBIB- p
8. Lattice partially balanced incomplete block design	LPBIB- p
9. Lattice unbalanced incomplete block design	LUBIB- p
10. Partially balanced incomplete block design	PBIB- p
11. Randomized block design	RB- p
12. Youden square design	YBIB- p
II Designs with Two or More Treatments	
A Factorial designs: designs in which all treatments are crossed	
1. Designs without confounding	
a. Completely randomized factorial design	CRF- pq
b. Generalized randomized block factorial design	GRBF- pq
c. Randomized block factorial design	RB- pq
2. Design with group-treatment confounding	
a. Split-plot factorial design	SPF- $p \cdot q$
3. Designs with group-interaction confounding	
a. Latin square confounded factorial design	LSCF- p^k
b. Randomized block completely confounded factorial design	RBCF- p^k
c. Randomized block partially confounded factorial design	RBPF- p^k
4. Designs with treatment-interaction confounding	
a. Completely randomized fractional factorial design	CRFF- p^{k-i}
b. Graeco-Latin square fractional factorial design	GLSFF- p^k
c. Latin square fractional factorial design	LSFF- p^k
d. Randomized block fractional factorial design	RBFF- p^{k-i}
B Hierarchical designs: designs in which one or more treatments are nested	
1. Designs with complete nesting	
a. Completely randomized hierarchical design	CRH- $pq(A)$
b. Randomized block hierarchical design	RBH- $pq(A)$
2. Designs with partial nesting	
a. Completely randomized partial hierarchical design	CRPH- $pq(A)r$
b. Randomized block partial hierarchical design	RBPF- $pq(A)r$
c. Split-plot partial hierarchical design	SPPH- $p \cdot qr(B)$
III Designs with One or More Covariates	
A Designs can include a covariate in which case the letters AC are added to the acronym as in the following examples.	
1. Completely randomized analysis of covariance design	CRAC- p
2. Completely randomized factorial analysis of covariance design	CRFAC- pq
3. Latin square analysis of covariance design	LSAC- p
4. Randomized block analysis of covariance design	RBAC- p
5. Split-plot factorial analysis of covariance design	SPFAC- $p \cdot q$

A wide array of designs is available to researchers. Hence, it is important to clearly identify designs in research reports. One often sees statements such as ‘a two-treatment, factorial design was used’. It should be evident that a more precise description is required. This description could refer to 10 of the 11 factorial designs in Table 1.

Analysis of Variance: Multiple Regression Approaches

Consider the following questions:

1. Is whether one has received the experimental treatment or the control ‘treatment’ predictive of one’s score on the dependent variable?
2. Do the experimental and control groups have different population means?
3. Is the group to which a participant was assigned predictive of that person’s score on the dependent variable?
4. Do the k groups have different population means?

Questions 1 and 2 appear to be mirror images of each other, essentially asking whether there is a relationship between the independent and dependent variables. The same can be said for questions 3 and 4. These appearances are *not* deceiving. As we shall see, there is a simple algebraic relationship between the correlation coefficient that is used to answer question 1 and the independent-means t ratio that is used to answer question 2. Similarly, there is a simple algebraic relationship between the multiple correlation coefficient that is used to answer question 3 and the overall F ratio that is used to answer question 4. At first glance, questions 1 and 3 appear to ask for more detailed analyses than do questions 2 and 4. That is, they ask for the prediction of individual participants’ scores, rather than simply comparing group means. This appearance *is* deceiving. The only information on which we can base our prediction of a given participant’s score is the group to which the participant was assigned or the group to which the participant naturally belongs. Hence, we must inevitably predict the same score for every individual in a given group and, if we are to minimize the average squared error of prediction, we must therefore focus on predicting the mean score for each group.

Consider two facts. First, for a two-group design, testing for the statistical significance of the correlation coefficient between a group-membership variable and a dependent variable yields the same conclusion as conducting an independent-means t Test of

the difference between the two means. Second, for a k -group design, testing for the statistical significance of the multiple correlation (see **R -squared**, **Adjusted R -squared**) between a set of $k - 1$ level-membership or contrast variables and the dependent variable yields the same conclusion as does the overall F ratio for the differences among the k means. These two facts do not imply, however, that there is nothing but mathematical elegance to be gained by comparing the two pairs of approaches. In particular, the correlation and regression approaches help us to appreciate that

1. large, highly significant t and F ratios may represent relationships that in fact account for rather small percentages of the total variance of a dependent variable;
2. the choice of alternative models for unequal- n factorial ANOVA designs (see **Type I**, **Type II and Type III Sums of Squares**; **Factorial Designs**) is not just a choice of error terms but also of the particular contrasts among the means that are being tested; and
3. while overall tests in unequal- n designs require the use of matrix algebra, single-degree-of-freedom tests of specific contrasts can be conducted by means of very simple algebraic formulae (see **Multiple Comparison Procedures**).

Let us demonstrate these facts and their consequences with a few examples.

Equivalence between Independent-means t and Dichotomy/Dependent Variable Correlation

Consider the data (Table 1) that are taken from Experiment 3 of Harris and Joyce [3].

From the above data, we compute $r_{XY} = -0.5396$. Applying the usual t Test for the significance of a correlation coefficient we obtain

$$\begin{aligned}
 t &= \frac{r_{XY}}{\sqrt{\frac{1 - r_{XY}^2}{N - 2}}} = \frac{-0.5396}{\sqrt{\frac{1 - 0.29117}{18}}} \\
 &= \frac{-0.5396}{0.1984} = -2.720
 \end{aligned} \tag{1}$$

2 Analysis of Variance: Multiple Regression Approaches

Table 1 Amount Allocated to 10-Interchange Partner as f(Allocation Task)

$X = \text{Allocn}$	$Y = \text{P10Outc}$	$X = \text{Allocn}$	$Y = \text{P10Outc}$
1	\$1.70	2	-\$1.50*
1	1.00	2	0.50
1	0.07	2	-1.50
1	0.00	2	-1.50
1	1.30	2	-1.00
1	3.00	2	2.10
1	0.50	2	2.00
1	2.00	2	-0.50
1	1.70	2	-1.50
1	0.50	2	0.00

Notes: $X = 1$ indicates that the group was asked to allocate the final shares of a prize directly. $X = 2$ indicates that they were asked how much of a room fee should be subtracted from each partner's individual contribution to determine his or her final share of the prize.

Source: Raw data supplied by first author of [3].

with 18 df , $p < 0.01$. Thus, we can be quite confident that having a higher score on X (i.e., being one of the groups in the expenses-allocation condition) is, in the population, associated with having a lower score on Y (i.e., with recommending a lower final outcome for the person in your group who worked on the most difficult problems).

Had we simply omitted the two columns of scores on X , the data would look just like the usual setup for a test of the difference between two independent means, with the left-hand column of Y scores providing group 1's recommendations and the right-hand column of Y scores giving group 2's scores on that dependent variable. Applying the usual formula for an independent-means t Test gives

$$\begin{aligned}
 t &= \frac{\bar{Y}_1 - \bar{Y}_2}{\sqrt{\frac{\sum (Y_1 - \bar{Y}_1)^2 + \sum (Y_2 - \bar{Y}_2)^2}{n_1 + n_2 - 2} \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}} \\
 &= \frac{1.177 - (-0.290)}{\sqrt{\frac{8.1217 + 18.0690}{18} (1/10 + 1/10)}} \\
 &= \frac{1.467}{0.53945} = 2.719
 \end{aligned} \tag{2}$$

with $n_1 + n_2 - 2 = 18$ df , $p < 0.01$. Thus, we can be quite confident that, in the population, groups who determine final outcomes only indirectly by

allocation of shares of the room fee give lower outcomes to the partner who deals with the most difficult anagrams than do groups who determine final outcomes directly. That is, having a high score on X is associated with having a lower Y score – which is what we concluded on the basis of the test of our correlation coefficient.

The formula for computing the independent-means t from the correlation coefficient is just the formula given earlier for testing the statistical significance of a correlation coefficient. Inverting that relationship gives us

$$r_{XY} = \frac{t}{\sqrt{t^2 + df}}, \tag{3}$$

where df = the degrees of freedom for the t Test, namely, $n_1 + n_2 - 2$.

Thus, in the present example,

$$\begin{aligned}
 r_{XY} &= \frac{-2.719}{\sqrt{7.3930 + 18}} \\
 &= \frac{-2.719}{5.03915} = -0.5396.
 \end{aligned} \tag{4}$$

An Application of the Above Relationship

An important application of the above relationship is that it reminds us of the distinction between statistical significance – confidence that we've got the *sign* of an effect right – and substantive significance – the estimated *magnitude* of an effect (see **Effect Size Measures**). For example, ASRT's *Environmental Scan of the RadiationTherapist's Workplace* found that the mean preference for a great work environment over a great salary was significantly greater among the staff-therapist-sample respondents who still held a staff or senior-staff therapist title than among those who had between the time of their most recent certification renewal and the arrival of the questionnaire moved on to another position, primarily medical dosimetrist or a managerial position within the therapy suite. The t for the difference between the means was 3.391 with 1908 df , $p < 0.001$. We can be quite confident that the difference between the corresponding population means is in the same direction. However, using the above formula tells us that the correlation between the still-staff-therapist versus moved-on distinction is $r = 3.391/\sqrt{1919.5} = 0.0774$. Hence, the distinction accounts for $(0.0774)^2 = 0.6\%$, which is less

than one percent of the variation among the respondents in their work environment versus salary preferences.

As this example shows, it is instructive to convert ‘experimental’ statistics into ‘correlational’ statistics. That is, convert t ’s into the corresponding r^2 ’s. The resulting number can come as a surprise; many of the r^2 ’s for statistically significant differences in means will be humbly low.

Equivalence Between Analysis of Variance and Multiple Regression with Level-membership or Contrast Predictors

Consider the hypothetical, but not atypical, data shown in Table 2.

Note that within each college, the female faculty members’ mean salary exceeds the male faculty members’ mean salary by \$5000–\$10 000. On the other hand, the female faculty is concentrated in the low-paying College of Education, while a slight majority of the male faculty is in the high-paying College of Medicine. As a result, whether ‘on average’ female faculty are paid more or less than male faculty depends on what sort of mean we use to define ‘on average’. An examination of the *unweighted mean* salaries (cf. the ‘Unweighted mean’ row toward the bottom of the table) of the males and females in the three colleges (essentially a per-college mean), indicates that female faculty make, on average, \$6667 more per year than do male faculty. If instead we compute for each gender the *weighted mean* of the three college means, weighting by the number of faculty members of that gender in each college, we

find that the female faculty members make, on average, \$6890 *less* than do male faculty members (see **Type I, Type II and Type III Sums of Squares**). These results are the same as those we would have obtained had we simply computed the mean salary on a per-individual basis, ignoring the college in which the faculty member taught (see **Markov, Andrei Andreevich**).

For the present purposes, this ‘reversal paradox’ (see **Odds and Odds Ratios**) [6] helps sharpen the contrast among alternative ways of using **multiple linear regression** analysis (MRA) to analyze data that would normally be analyzed using ANOVA. This, in turn, sheds considerable light on the choice we must make among alternative models when carrying out a factorial ANOVA for unbalanced designs. In an unbalanced design, the percentage of the observations for a given level of factor A differs across the various levels of factor B. The choice we must make is usually thought of as bearing primarily on whether a given effect in the ANOVA design is statistically significant. However, the core message of this presentation is that it is also – and in my opinion, more importantly – a choice of what kinds of means are being compared in determining the significance of that effect. Specifically, a completely uncorrected model involves comparisons among the *weighted means* and is thus, for main effects, equivalent to carrying out a one-way ANOVA for a single factor, ignoring all other factors. Furthermore, the analysis makes no attempt to correct for confounds with those other factors. A completely uncorrected model is equivalent to testing a regression equation that includes only the contrast variables for the particular effect being tested. A fully corrected model

Table 2 Mean Faculty Salary* at Hypothetical U as f (College, Gender)

Educn-F	3	2	23.000	20
	3	2	25.000	40
	3	2	27.000	20

involves comparisons among the *unweighted* means. A fully corrected model is equivalent to testing each effect on the basis of the increment to R^2 that results from adding the contrast variables representing that effect last, after the contrast variables for all other effects have been entered. And in-between models, where any given effect is corrected for confounds with from zero to all other effects, involve contrasts that are unlikely to be interesting and correspond to questions that the researcher wants answered. I will note one exception to this general condemnation of in-between models – though only as an intermediate

step along the way to a model that corrects only for interactions of a given order or lower.

You can replicate the analyses I am about to use to illustrate the above points by entering the following variable names and values into an SPSS™ data editor (aka .sav file). One advantage of using hypothetical data is that we can use lots of identical scores and thus condense the size of our data file by employing the ‘Weight by’ function in SPSS (Table 3).

One-way, Independent-means ANOVA

First, I will conduct a one-way ANOVA of the effects of College, ignoring for now information about the gender of each faculty member. Submitting the following SPSS commands

```
Title Faculty Salary example .
Weight by nij .
Subtitle Oneway for college effect .
Manova sal by college (1,3) /
  Print = cellinfo (means) signif
    (univ) design (solution) /
  Design /
  Contrast (college) = special
    (1 1 1, -1 2 -1, 1 0 -1) /
Design = college (1), college (2).
Weight off .
```

yields (in part) the output as shown in Tables 4 and 5.

Notice that the means are identical to those listed in the ‘Weighted mean’ column of the data table shown previously.

Table 4 Cell means and standard deviations

Variable.. SAL		Salary (thousands of dollars)		
FACTOR	CODE	Mean	Std. Dev.	N
COLLEGE	Engineering	30.417	2.028	60
COLLEGE	Medicine	52.000	4.264	100
COLLEGE	Education	24.000	2.462	100
For entire sample		36.250	13.107	260

Table 5 Tests of significance for SAL using unique sums of squares; analysis of variance – design 1

Source of Variation	SS	DF	MS	F	Sig of F
WITHIN CELLS	2642.58	257	10.28		
COLLEGE	41854.17	2	20927.08	2035.23	0.000

To accomplish the same overall significance test using MRA, we need a set of two predictor variables (more generally, $k - 1$, where k = number of independent groups) that together completely determine the college in which a given faculty member works. There are many alternative sets of predictor variables (see **Regression Model Coding for the Analysis of Variance and Type I, Type II and Type III Sums of Squares**), but it is generally most useful to construct *contrast variables*. This is accomplished by choosing a set of $k - 1$ interesting or relevant contrasts among our k means. We then set each case's score on a given contrast equal to the contrast coefficient that has been assigned to the group within which that case falls. Let us use the contrast between the high-paying College of Medicine and the other two colleges as our first contrast (labeled 'medvoth' in our SPSS data file) and the contrast between the Colleges of Engineering and Education (labeled 'engveduc') as our second contrast. This yields the expanded .sav file as shown in Table 6.

Recall that contrast coefficients are defined only up to a multiplicative constant. For example, $\mu_{\text{Med}} - 0.5\mu_{\text{Engn}} - 0.5\mu_{\text{Educ}} = 0$ if and only if $2\mu_{\text{Med}} - \mu_{\text{Engn}} - \mu_{\text{Educ}} = 0$. The 'extra' three columns in the expanded .sav file above give contrasts for the Gender main effect and the interaction between Gender and each of the two College contrasts; more about these later. We then run an MRA of Salary predicted from

MedvOth and EngvEduc, for example, by submitting the following SPSS commands.

```
Weight off .
Subtitle One-way for College and
      College-First Sequential .
Weight by nij .
Regression variables = sal mfcontr
      medvoth engveduc gbcoll1 gbcoll2 /
Statistics = defaults cha /
Dep = sal / enter medvoth engveduc /
      enter gbcoll1 gbcoll2 /
      enter mfcontr/.
Weight off .
```

Only the first step of this stepwise regression analysis – that in which only the two College contrasts have been entered – is relevant to our one-way ANOVA. I will discuss the remaining two steps shortly.

The resulting SPSS run yields, in part, the output as shown in Tables 7 and 8.

The test for the statistical significance of R^2 consists of comparing $F = R^2/(k - 1)/(1 - R^2)/$

COLLEGE(1)	36877.60	1	36877.60	3586.47	0.000
COLLEGE(2)	1544.01	1	1544.01	150.16	0.000

$(N - k)$ to the critical value for an F with $k - 1$ and $N - k$ *df*, yielding the F of 2035.228 reported in the above table, which matches the overall F for College from our earlier ANOVA table.

But, what has been gained for the effort involved in defining contrast variables? The MRA output continued with the listing of regression coefficients (Table 9) and tests of the statistical significance thereof.

We want to compare these MRA-derived t Tests for the two contrasts to the corresponding ANOVA output (Table 10) generated by our Contrast subcommand in conjunction with the expanded design statement naming the two contrasts.

Recall that the square of a t is an F with 1 *df* in the numerator. We see that the t of 59.887 for the significance of the difference in mean salary between the College of Medicine and the average of the other two colleges corresponds to an F of 3586.45. This value is equal, within round-off error, to the ANOVA-derived value. Also, the square of the t for the Engineering versus Education contrast, $(12.254)^2 =$

150.16, matches equally closely the ANOVA-derived F . Notice, too, that the unstandardized regression coefficients for the two contrasts are directly proportional to signs and magnitudes of the corresponding contrasts: 3.208 (the regression coefficient for EngvEduc) is exactly half the difference between those two means, and 8.264 (the coefficient for MedvOth) exactly equals one-sixth of $2(\text{mean for Medicine}) - (\text{mean for Engineering}) - (\text{mean for Education})$. The divisor in each case is the sum of the squared contrast coefficients.

Factorial ANOVA via MRA

We will add to the data file three more contrast variables: MFContr to represent the single-*df* Gender effect and GbColl1 and GbColl2 to represent the interaction between Gender and each of the previously selected College contrasts. We need these variables to be able to run the MRA-based analysis. More importantly, they are important in interpreting the particular patterns of differences among means

that are responsible for statistically significant effects. See the article in this encyclopedia on **regression model coding in ANOVA** for details of how to compute coefficients for an interaction contrast by cross multiplying the coefficients for one contrast for each of the two factors involved in the interaction. We can then test each of the two main effects and the interaction effect by testing the statistical significance of the increment to R^2 that results from adding the contrast variables representing that effect to the regression equation. This can be done by computing

$$F_{\text{incr}} = \frac{\frac{(\text{Increase in } R^2)}{(\text{number of predictors added})}}{\frac{(R^2 \text{ for full model})}{(N - \text{total \# of predictors} - 1)}} \quad (5)$$

or by adding 'Cha' to the statistics requested in the SPSS Regression command.

For equal- n designs

1. all sets of mutually orthogonal contrasts are also uncorrelated;
2. the increment to R^2 from adding any such set of contrasts is the same, no matter at what point they are added to the regression equation; and

3. the F s for all effects can be computed via simple algebraic formulae; see [1], any other ANOVA text, or the article on factorial ANOVA in this encyclopedia.

However, when n s are unequal (unless row- and column-proportional),

1. Orthogonal contrasts (sum of cross-products of coefficients equal zero) are, in general, not uncorrelated;
2. The increment to R^2 from adding any such set of contrasts depends on what other contrast variables are already in the regression equation; and
3. Computing the F for any multiple- df effect requires the use of matrix algebra.

To illustrate this context dependence, consider the following additional output (Table 11) from our earlier stepwise-MRA run. There, we entered the College contrasts first, followed by the interaction contrasts and then by the Gender main-effect contrast, together with a second stepwise-MRA run in which the order of entry of these effects is reversed (Table 11, 12).

^aDependent Variable: Salary (thousands of dollars).

Order of entry of an effect can affect not only the magnitude of the *F* for statistical significance but even our estimate of the direction of that effect, as shown in the regression coefficients for Gender in the various stages of the ‘Gender, C x G, College’ MRA (Table 13).

Notice that the Gender contrast is positive, indicative of higher salaries for males, when Gender is the first effect entered into the equation, but negative when it is entered last. Notice, also that the test for significance of a regression coefficient in the full model is logically and arithmetically identical to the test of the increment to R^2 when that contrast variable is the last one added to the regression equation. This is of course due to the fact that different contrasts are being tested in those two cases: When Gender is ‘first in,’ the contrast being tested is the difference between the weighted means, and the *B* coefficient for MFCONTR equals half the difference (\$6890) between the mean of the 155 males’ salaries and the mean of the 105 females’ salaries. When Gender is ‘last in,’ the contrast being tested is the difference between the unweighted means, and the *B* coefficient for MFCONTR equals half the difference (−\$6667) between the mean of the three college means for males and the mean of the three college means for females. Each of these comparisons is the right answer to a different question.

The difference between weighted means – what we get when we test an effect when entered first –

is more likely to be relevant when the unequal *ns* are a reflection of preexisting differences in representation of the various levels of our factor in the population. Though even in such cases, including the present example, we will probably also want to know what the average effect is within, that is, controlling for the levels of the other factor. Where the factors are manipulated variables, we are much more likely to be interested in the differences among unweighted means, because these comparisons remove any confounds among the various factors.

But, what is being tested when an effect is neither first nor last into the equation? A little known, or seldom remarked upon, aspect of MRA is that one can, with the help of a bit of matrix algebra, express each sample regression coefficient as a linear combination of the various subjects’ scores on the dependent variable. See section 2.2.4 of Harris [2] for the details. But when we are using MRA to analyze data from an independent-means design, factorial, or otherwise, every subject in a particular group who receives a particular combination of one level of each of the factors in the design has exactly the same set of scores on the predictor variables. Hence, all of those subjects’ scores on *Y* must be given the same weight in estimating our regression coefficient. Thus, the linear combination of the individual *Y* scores that is used to estimate the regression coefficient must perforce also be a linear combination of contrasts among the means and therefore also a contrast among

Table 14 Solution Matrix for Between-Subjects Design

1-COLLEGE		2-GENDER		PARAMETER			
FACTOR							
1	2	1	2	3	4	5	6
1	1	-0.707	0.866	-0.500	0.707	0.866	-0.500
1	2	-0.707	0.866	-0.500	-0.707	-0.866	0.500
2	1	-0.707	0.000	1.000	0.707	0.000	1.000
2	2	-0.707	0.000	1.000	-0.707	0.000	-1.000
3	1	-0.707	-0.866	-0.500	0.707	-0.866	-0.500
3	2	-0.707	-0.866	-0.500	-0.707	0.866	0.500

those means. SPSS's MANOVA command gives, if requested to do so by including 'Design (Solution)' in the list of requested statistics, the contrast coefficients for the contrasts it actually tests in any given analysis. For instance, for the full-model analysis of the faculty salary data, the solution matrix is as shown in Table 14.

Thus, the full-model analysis tests the contrasts we specified, applied to the unweighted means. For example, the Gender effect in column 4 compares the average of the three male means to the average of the three female means. Consider another example. We specify 'Method = Sequential' and indicate by specifying 'Design = College, Gender, Gender by College' that we want College to be tested first (uncorrected for confounds with Gender or $G \times C$) and Gender to be tested second (corrected for confounds with College but not with $G \times C$). The column of the solution matrix (not reproduced here) corresponding to the Gender effect tells us that the contrast actually being tested is

$$\begin{aligned} &0.758\mu_{\text{Engnr-M}} + 2.645\mu_{\text{Med-M}} \\ &+ 2.645\mu_{\text{Educ-M}} - 0.758\mu_{\text{Engnr-F}} \\ &- 2.645\mu_{\text{Med-F}} - 2.645\mu_{\text{Educ-F}}. \end{aligned}$$

On the other hand, if the interaction effect is entered first, followed by Gender, the contrast being tested is

$$\begin{aligned} &4.248\mu_{\text{Engnr-M}} + 3.036\mu_{\text{Med-M}} \\ &+ 0.087\mu_{\text{Educ-M}} - 0.666\mu_{\text{Engnr-F}} \\ &- 1.878\mu_{\text{Med-F}} - 4.827\mu_{\text{Educ-F}}. \end{aligned}$$

Finally, whenever Gender is entered first, the contrast we are testing is

$$2.807\mu_{\text{Engnr-M}} + 4.083\mu_{\text{Med-M}}$$

$$\begin{aligned} &+ 1.021\mu_{\text{Educ-M}} - 0.377\mu_{\text{Engnr-F}} \\ &- 1.507\mu_{\text{Med-F}} - 6.028\mu_{\text{Educ-F}} \\ &= 7.91[(55\mu_{\text{Engnr-M}} + 80\mu_{\text{Med-M}} \\ &+ 20\mu_{\text{Educ-M}})/155 - (5\mu_{\text{Engnr-F}} \\ &+ 20\mu_{\text{Med-F}} + 80\mu_{\text{Educ-F}})/105], \quad (6) \end{aligned}$$

that is, the difference between the weighted means for males versus females.

Kirk's [4] and Maxwell and DeLaney's [5] texts provide explanations for some of the contrasts that arise when testing partially corrected, 'in-between,' effects. For example, effects involving contrasts among means weighted by the harmonic mean of the cell sizes for the various levels of the other factor. However, the chances that such contrasts would be of any interest to a researcher seem to the author to be remote. It seems advisable, therefore, to choose between conducting a full-model analysis, the default in SPSS' MANOVA, or testing each effect uncorrected for any other effects. This is one of the options provided by SAS as *Type I Sums of Squares*. This also can be accomplished in SPSS by carrying out one run for each effect that is to be tested and specifying that effect as the first to be entered into the equation.

If you do decide to conduct a sequential analysis of an unequal- n factorial design, you will need to be careful about what means to compare when describing your results. If you ask SPSS to print out marginal means by using the Omeans subcommand, as in 'Omeans = Tables Gender, College,' there's no need to print means for the highest-order interaction. This follows because it duplicates the output of 'Print = Cellinfo (Means)'. SPSS will report both the weighted and the unweighted means for each selected effect, as shown in Table 15.

Table 15 Analysis of variance design 1

Combined Observed Means for GENDER			
Variable.. SAL			
GENDER			
Males	WGT.		39.03226
	UNWGT.		33.33333
Females	WGT.		32.14286
	UNWGT.		40.00000
Combined Observed Means for COLLEGE			
Variable.. SAL			
COLLEGE			
Engineer	WGT.		30.41667
	UNWGT.		32.50000
Medicine	WGT.		52.00000
	UNWGT.		55.00000
Educatio	WGT.		24.00000
	UNWGT.		22.50000

For whichever effect is tested first in your sequential analysis, you should compare the weighted means labeled 'WGT,' because those are what the significance test actually tested. The effect that is tested last should be described in terms of the unweighted means labeled 'UNWGT'. And describing any effect that is tested in an in-between position requires that you (a) describe what contrasts were actually tested in deriving the overall significance test for the effect and the tests of follow-up contrasts, using the entries in the solution matrix to guide you, and (b) use the coefficients in that solution matrix to compute with a calculator the direction and magnitude of each component contrast, because neither the weighted nor the unweighted means provided by SPSS were the ones used to estimate this in-between contrast.

There is one exception to the above abjuration of in-between contrasts that is likely to be useful and is usually referred to as the 'experimental' order. In this case, each main effect is corrected for the other main effects but not for any interactions. Two-way interactions are corrected for all main effects and the other two-way interactions, but not for 3-way or higher-order interactions, and so on. This order of testing holds out the promise of finding that none of the interactions higher than a given order, for example, no three- or four-way interactions are large or statistically significant and thus being able to simplify the model used to explain responses. However, once all the effects that are to be retained in the simplified model have

been determined, each retained effect should then be retested, correcting each for all other retained effects.

Hand Computation of Full-model Contrasts

Our exploration of unequal- n factorial designs has relied on the use of computer programs such as SPSS. However, another little-remarked-upon aspect of such designs is that the full-model (fully corrected) test of any single- df contrast can be conducted via the straightforward (if sometimes tedious) formula,

$$F_{\text{contr}} = \frac{SS_{\text{contr}}}{MS_w}, \text{ where}$$

$$SS_{\text{contr}} = \frac{\left(\sum_{j=1}^{n_{\text{groups}}} c_j \bar{Y}_j \right)^2}{\sum c_j^2 / n_j}. \quad (7)$$

The important thing to keep in mind about this formula is that a contrast coefficient must be applied to and a c_j^2/n_j term computed for each individual cell in the design, that is, each combination of a level of each of the factors. Thus, for example, SS_{contr} for the main effect of gender in the faculty salary example would be computed as

$$\frac{[(1)\bar{Y}_{\text{Engnr-M}} + (1)\bar{Y}_{\text{Med-M}} + (1)\bar{Y}_{\text{Educ-M}} + (-1)\bar{Y}_{\text{Engnr-F}} + (-1)\bar{Y}_{\text{Med-F}} + (-1)\bar{Y}_{\text{Educ-F}}]^2}{1/55 + 1/80 + 1/20 + 1/5 + 1/20 + 1/80}.$$

Significance tests for multiple- df effects such as the College main effect require the use of matrix algebra or a computer program.

Ansari–Bradley Test

Let $(x_1, x_2, \dots, x_n)$ and $(y_1, y_2, \dots, y_m)$ be independent random samples from two distributions having known medians or a common median but potentially different variances, $\text{var}(X)$ and $\text{var}(Y)$.

The parameter of interest is the ratio of variances, $\gamma = \text{var}(X)/\text{var}(Y)$. The usual hypothesis to be nullified is that $\gamma = 1$. The substantive (alternative) hypothesis is either that $\gamma < 1$, that $\gamma > 1$, or that γ differs from 1.

For the Ansari–Bradley test [1], the combined set of $(n + m)$ observations first is ordered from smallest to largest after having been adjusted for different population medians. Then, ranks are assigned to the observations as follows. The largest and smallest observations are assigned ranks of 1. The second-largest and second-smallest observations are assigned ranks of 2. This process is continued until all observations have been assigned a rank.

The test statistic is the sum of the ranks assigned to the observations in the smaller of the two samples, $g = \text{Sum}(R_j)$, $j = 1, \dots, m$. By convention the smaller sample is identified as the sample from the Y distribution and, hence, the variance in this population is the denominator in the variance ratio γ .

Naively, the statistic g will be small if the dispersion in the Y population is great and large if the population dispersion is limited. Thus, larger values of g are consistent with $\gamma > 1$ and smaller values of g are consistent with $\gamma < 1$.

Tail probabilities for the null distribution of g have been tabulated [3] for a range of values of m and n where n is no smaller than m . A normal approximation to the null distribution is used for larger samples, for example, when $(n + m)$ is greater than 20 [3].

Example A random sample of 20 tenth-graders is randomly divided into two samples, each of size 10.

For the students in one of the samples, mathematics achievement is assessed using Edition 2001 of a standard test. Students in the second sample are assessed with Edition 2003 of the test. Scaled scores on the two editions are known to have the same median. However, there is suggestive evidence in earlier studies that the variability in scores on Edition 2003 may be greater.

The sampled test scores are given in the first two rows of Table 1. Their Ansari–Bradley ranks appear in the third and fourth rows.

The tied observations (91s, 94s, 102s) were awarded the average rank for each set of ties. The sum of ranks for the Edition 2003 sample is in the predicted direction: that is, $47.5 < 62.5$. Under the null hypothesis, the tabulated probability of a rank sum of 47 or smaller is 0.10 and that of a rank sum of 48 or smaller is 0.13. We would be unlikely to reject the null hypothesis on this evidence.

The `exactRankTests` package in the statistical programming language *R* (www.R-project.org) includes a function `ansari.exact` to carry out the test and, optionally, to construct a confidence interval for γ . The algorithm used in that function yields a P value of 0.14 for these data.

Summary

The validity of the Ansari–Bradley test [1] requires that the two population medians be known or that they be known to be equal. The results of the test can be misleading if, as is most often the case, the populations differ in location by an unknown amount. An alternative test based on the squared ranks of the absolute deviations of observations about their (estimated) population means does not require equivalence or knowledge of population medians and is described in [2]. This test, the *Conover test*, is included in the *StatXact* program (www.cytel.com) and see **Exact Methods for Categorical Data**.

Arbuthnot, John

Born: April 29, 1667, in Kincardineshire, Scotland.

Died: February 27, 1735, in London, England.

John Arbuthnot was born in the parish of Arbuthnott, Kincardineshire, Scotland. His parents were Alexander Arbuthnott, an Anglican clergyman, and Margaret Lammy Arbuthnott. As you can see, the traditional spelling of the name included an additional 't'. Arbuthnot pursued his education in England and Scotland and began his writing career while studying in London. In 1696, he received his Doctor of Medicine degree from St Andrews. He was married, and fathered four children [1, 3].

Arbuthnot became well-known in London for his skill as a physician. In 1704, Arbuthnot was elected a Fellow of the Royal Society. In 1705, he was appointed Physician Extraordinary to Queen Anne and in 1709, became her Physician Ordinary. In 1710, Arbuthnot was elected a fellow of the Royal College of Physicians. However, it is for his satirical writings that Arbuthnot is best known. He counted among his friends Alexander Pope, Jonathan Swift, John Gay, and Thomas Parnell. In 1714, these gentlemen established the Scriblerus Club. The remit of the Club was to satirize pedantry and bad poetry. In addition to his literary endeavors, Arbuthnot, over a period of 40 years, wrote eight works of a scientific nature. Three of these works dealt with mathematics in some form [2, 3].

Mathematical Works

Laws of Chance

Arbuthnot's first book, entitled *Of the Laws of Chance*, was published anonymously in 1692; it was a translation of Christiaan Huygens's *De ratiociniis in ludo Aleae* [2, 3]. Huygens intentionally left two problems unsolved in his book, and in his translation, Arbuthnot offered solutions to the problems. His solutions were later replicated by James Bernoulli [2]. However, the primary intent of the book was to expose the general reader to the uses of probability in games of chance as well as in other endeavors such as politics (see **Probability: Foundations** of).

This book is often considered to be of less importance than the two subsequent books Arbuthnot was to devote to mathematical topics [2, 3].

Usefulness of Mathematics

In 1701, Arbuthnot published a second treatise on mathematics, again anonymously, entitled *An Essay on the Usefulness of Mathematical Learning*, subtitled *In a Letter from a Gentleman in the City to His Friend in Oxford* [3]. In this work, Arbuthnot reflected upon the intellectual and practical benefits of learning mathematics. As mathematics was neglected by most students of the time, who believed that it was too difficult a subject, Arbuthnot argued that mathematicians had provided ample simplifications and examples of calculations that would allow anyone to perform them. Arbuthnot ends his treatise by suggesting that the best ways to teach mathematics are by practical demonstrations and progressing from simple to complex problems [1].

Arguing for Divine Providence

In 1710, Arbuthnot published his third mathematical treatise. Entitled *An Argument for Divine Providence, taken from the Constant Regularity observed in the Births of both Sexes*, this treatise represents Arbuthnot's efforts to demonstrate the usefulness of mathematics as well as the existence of God [2, 3]. Using probability formulas, Arbuthnot argued that the existence of God was revealed by the prevalence of male births found in the official statistical summaries of births and deaths. Such dominance was not due to chance but was a reflection of God's desire to ensure the continuation of the human race. Given that more males than females were likely to suffer from disease and death, such dominance would ensure that there would be a sufficient number of males who would marry and father children.

These three works did not significantly contribute to the development of statistical analysis but, rather, reflect Arbuthnot's ever-searching mind [2, 3].

Area Sampling

In an area sample, the primary sampling units are well-defined fractions of the earth's surface [2]. The sampling frame, also referred to as the area frame, is in fact a map that has been subdivided into a certain number of mutually exclusive and exhaustive areas. Of course, the actual sampling frame need not be in the form of a map. In practice, the sampling frame will usually consist of a list of the areas from which the sample is to be drawn.

Any partition of the area frame into area segments will yield unbiased estimates of the population parameters of interest. However, the efficiency of the estimators can differ greatly between partitions. More specifically, the design of an efficient area sample requires that areas are as equal in size as possible [2].

Area samples can be used for several purposes. In agricultural and forestry research, they are often employed to study the characteristics of the land covered by the sampled area. In this context, area samples are, for example, used to study the number of acres in certain crops, the number of acres covered by forests, or the number of acres under urban development. Area samples are also used in behavioral research [3] when no complete or up-to-date sampling frame is available for the observational units (households, individuals, businesses, etc.) that are of actual interest. In such a case, information is collected from all observational units within the sampled areas. Area samples have, for example, been used for this purpose in the context of the United States census as well as in other countries that do not maintain current lists of residents. However, even if current population registers are available, area sampling is sometimes used in the first stage of two-stage sampling procedure for practical reasons. For example, the Belgian General Election studies [1] use a two-stage sample from the population to collect information about political and related attitudes. In the

first stage, a random sample of villages is drawn, and then within the sampled villages, random samples of individuals are drawn. The latter sampling design is used to reduce the interviewer workload by concentrating respondents in certain areas and hence reducing travel distances.

A very important issue with respect to the use of area sampling is the accurate definition of the primary sampling units, that is the areas, as well as the development of a set of rules that associates the elements of the population under study with the areas. In behavioral research, administrative boundaries (villages, counties, etc.) are often useful in determining the boundaries of the primary sampling units, provided the size of these administrative areas is suitable for the purpose of the research. Individuals and households can be associated with the area segments through their primary residence. The latter is, however, not always straightforward because some individuals or households might have multiple residences.

Arithmetic Mean

The arithmetic mean, usually referred to as the mean, is the most commonly used measure of central tendency or location. It is often denoted by $\bar{X}$ or M (the latter symbol is recommended by the American Psychological Association [1]). The mean is defined as the sum of a set of scores divided by the number of scores, that is, for a set of values, $X_1, X_2, \dots, X_n$ ($i = 1, 2, \dots, n$),

$$\bar{X} = \frac{\sum_i X_i}{n}. \quad (1)$$

Thus, for example, the arithmetic mean of 15 and 10 is $25/2 = 12.5$.

One advantage that the mean has over some other measures of central tendency is that all the members of the set of scores contribute equally to its calculation. This can also be a drawback, however, in that the mean can be seriously affected by extreme scores. As a simple illustration, consider the five values 5, 10, 15, 20, and 25, for which both the mean and median are 15. When a much larger value is added to the set, say 129, the mean becomes 34 while the median is 17.5. If, instead of

129 the new number had been 27, then the mean would have been 17, though the median would still be 17.5. However, the problem of outliers can be ameliorated by more robust versions of the mean such as **trimmed means** and Winsorized means (see **Winsorized Robust Measures**) [2], or by using the **harmonic** or **geometric means**.

Another disadvantage of the arithmetic mean is that, with discrete numbers, it may not appear to be a sensible figure given the nature of the variable of interest – for example, if the mean number of children in a class comes out at 35.7.

Despite these shortcomings, the mean has desirable properties, which account for its widespread use for describing and comparing samples both as a summary measure and in traditional inferential methods, such as t Tests.

Ascertainment Corrections

Statistical Theory

The aim of genetic epidemiologists is to characterize the population of interest, which is straightforward when data from a random sample of the population are available. However, by either accident or design, it may be that a random sample is not available. Two examples will clarify these situations. First, suppose an investigator attempts to obtain magnetic resonance imaging scans to assess body circumference. Subjects with very large circumference will not fit into the scanner, so their data will not be available, which is a case of data systematically missing by accident. Second, consider a twin study of depression in which the only pairs available are those in which at least one twin has major depressive disorder, because ascertainment has been through hospital registration. Here, the data are missing by design. Both cases may require correction for ascertainment. At first sight, these corrections may seem technically challenging, but for the most part they are based on simple principles, which involve correctly specifying the probability density function (pdf) for the sample as well as for the population. Sometimes it is necessary to provide estimates of population parameters in order to compute the appropriate correction.

Maximum likelihood estimation typically proceeds by estimating the parameters of the distribution to find the values that maximize the joint likelihood of the observed data points. For example, if it is assumed that a set of scores were drawn from a population with a normal distribution, the mean μ and the variance σ^2 may be estimated. Of primary importance here is that the normal distribution is a pdf, and that the sum over all possible observed points, which we write as the integral from $-\infty$ to $+\infty$, equals unity, that is,

$$\int_{-\infty}^{\infty} \phi(x) dx = 1, \quad (1)$$

where

$$\phi(x) = \frac{e^{-\frac{(x-\mu)^2}{\sigma^2}}}{\sqrt{2\pi}}. \quad (2)$$

In the event that only persons with a score of t or above are available (perhaps due to preselection of

the sample or some malfunction of equipment such that those with scores below t had their data deleted), then the sample mean and variance will be biased estimates of the population statistics. Similarly, maximum likelihood estimates of the population mean and variance obtained by maximizing the likelihood will be biased in the absence of correction. Essentially, the likelihood must be renormalized so that the probability of all possible outcomes (the integral of possible scores from $-\infty$ to $+\infty$) equals unity. For a sample with scores restricted to be above threshold t , the ascertainment correction equals the proportion of the distribution that remains, which is:

$$\int_t^{\infty} \phi(x) dx. \quad (3)$$

so the likelihood of an observed score $x > t$ becomes:

$$\frac{\phi(x)}{\int_t^{\infty} \phi(x) dx}. \quad (4)$$

An ascertainment correction of this type can be made easily within a program such as Mx [3] using its `\mnor` function in the formula for the weight. Note that knowledge of the threshold for ascertainment, t , is required to define the correction (*see Software for Behavioral Genetics*).

Three complications to the above situation are regularly encountered in **twin studies** and family studies (*see Family History Versus Family Study Methods in Genetics*). First, selection of families may be based on either one or both members of a pair of relatives. Second, the analysis of binary or ordinal data requires somewhat special treatment. Third, the variable that is used to select the twins is sometimes not the one that is the focus of the analysis.

Consider the analysis of data collected from pairs of twins, under the assumption that the distribution of the pairs of scores is bivariate normal in the population. In the absence of ascertainment, the likelihood of a pair of scores is simply:

$$\phi(x_1, x_2), \quad (5)$$

where $\phi(x_1, x_2)$ is the multivariate normal probability density function (*see Catalogue of Probability Density Functions*) given by

$$|2\pi \Sigma|^{-2m/2} \exp \left[-\frac{1}{2} (\mathbf{x}_i - \boldsymbol{\mu}_i)' \Sigma^{-1} (\mathbf{x}_i - \boldsymbol{\mu}_i) \right], \quad (6)$$

2 Ascertainment Corrections

where m is the number of variables, Σ is their population covariance matrix; μ_i is their (column) vector of population means; and $|\Sigma|$ and Σ^{-1} respectively denote the determinant and inverse of the matrix Σ . If pairs are ascertained such that twin 1's score is above threshold, $x_1 > t$, then the ascertainment correction is identical to that in 3 above. When pairs are ascertained if and only if they are both above threshold t , then the ascertainment correction is given by the double integral:

$$\int_t^\infty \int_t^\infty \phi(x_1, x_2) dx_2 dx_1. \quad (7)$$

Revision of these formulas to cases in which twins are selected for being discordant, for example, where twin 1 is above threshold t and twin 2 is below threshold $-u$, would be achieved by changing the limits of the integrals. Of particular note in situations of this sort is that the population threshold t must be estimated from other sources, since the estimate of the correlation between relatives depends heavily on this value.

Correction for the third complication mentioned above, where the variable of interest is not the same as the variable used for ascertainment, is also straightforward. The ascertainment correction remains unchanged, but the likelihood must be written as the joint likelihood of the ascertainment variable and the variable of interest, corrected for ascertainment. If the variable of interest is denoted by y_1 and y_2 for twin 1 and twin 2, and the variable on which ascertainment is based is x_1 in twin 1 and x_2 in twin 2, then the likelihood may be written as

$$\frac{\phi(x_1, x_2, y_1, y_2)}{\int_t^\infty \int_t^\infty \phi(x_1, x_2) dx_2 dx_1} \quad (8)$$

when ascertainment is for pairs concordant for being above threshold t . The most important thing to note in this case is that the correct expression for the likelihood involves the joint likelihood of both the ascertainment variable and the variable of interest. If the ascertainment variables x_1 and x_2 are both independent of both y_1 and y_2 , it would not be necessary to correct for ascertainment, and uncorrected univariate analysis of y_1 and y_2 would yield the same results.

Binary Data

A popular approach to the analysis of binary data collected from pairs of relatives is to assume that there is an underlying bivariate normal distribution of liability in the population (*see Liability Threshold Models*). The binary observed variable arises as a sort of measurement artifact in that those above threshold t get a score of 1 and those below get a score of 0. The aim of the approach is to estimate familial resemblance as a **tetrachoric correlation**, which is the correlation between the relatives' underlying liability distributions. Here we can classify sampling scenarios by reference to the probability that an individual is ascertained given that they are affected. This probability, often referred to as π [2], identifies two special situations at its extremes. Any study that has obtained at least one pair cannot have an ascertainment probability $\pi = 0$, but we can use the limit as $\pi \rightarrow 0$ for cases in which it is very unlikely that a subject is ascertained. In this case, it would be extremely unlikely to ascertain both members of the pair, and the scheme is known as *single ascertainment*. The appropriate correction for ascertainment here is simply the probability that one member of the pair is ascertained, that is, (3). This situation might be encountered if patients were ascertained through a clinic setting where it is very unlikely that their relative attends the same clinic, and the relatives are obtained for study purely through information provided by the patient.

At the other extreme, the probability of ascertainment given affected status is unity, which is known as *complete ascertainment*. One circumstance where this may be encountered is where twin pairs are ascertained through records of all hospitals in a country, and where affected status inevitably leads to hospitalization. In this case, the only pairs that are missing from the sample are those in which neither relative is affected. The ascertainment correction would therefore be

$$1 - \int_{-\infty}^t \int_{-\infty}^t \phi(x_1, x_2) dx_2 dx_1. \quad (9)$$

which is equal to the sum of the probabilities of observing the three remaining outcomes for a relative pair:

$$\int_{-\infty}^t \int_t^\infty \phi(x_1, x_2) dx_2 dx_1$$

$$\begin{aligned}
 & + \int_t^\infty \int_{-\infty}^t \phi(x_1, x_2) dx_2 dx_1 \\
 & + \int_t^\infty \int_t^\infty \phi(x_1, x_2) dx_2 dx_1. \quad (10)
 \end{aligned}$$

The situation in which sampling is at neither of these extremes, $0 < \pi < 1$, is known as *incomplete ascertainment* [1]. Treatment of this scenario is more complicated because it depends on whether the pair has been ascertained through one or both members of the pair. For singly ascertained pairs it is

$$\frac{\pi}{2\pi \int_{-\infty}^t \phi(x_1) dx_1 - \pi^2 \int_t^\infty \int_t^\infty \phi(x_1, x_2) dx_2 dx_1} \quad (11)$$

and for pairs in which both members were ascertained it is

$$\frac{\pi(2 - \pi)}{2\pi \int_{-\infty}^t \phi(x_1) dx_1 - \pi^2 \int_t^\infty \int_t^\infty \phi(x_1, x_2) dx_2 dx_1}. \quad (12)$$

An application using all of these corrections was described by Sullivan et al. in their **meta-analysis** of twin studies of schizophrenia [4].

Assortative Mating

Assortative mating is a departure from random mating in which like individuals preferentially mate with each other (positive assortative mating, or homogamy) or unlike individuals preferentially mate with each other (negative assortative mating, or disassortative mating). Cross-characteristic assortative mating is also possible, wherein individuals having a certain level of phenotype (observable characteristic) A mate with others having a certain level of phenotype B.

Since the early twentieth century, the degree of assortative mating has been expressed by the correlation r between the phenotypic values of mated individuals (*see Correlation Issues in Genetics Research*). In the earliest example of positive assortative mating, Pearson and Lee [5] calculated a ‘significant’ r of 0.093 ± 0.047 for stature on the basis of Table 1 provided by Galton [2]:

In addition, as shown in Table 2, Pearson and Lee [5] found in their own data positive direct and cross-assortative mating for stature, arm span, and forearm length:

Table 1 Heights of husbands and wives

		Husband			Totals
		Short	Medium	Tall	
Wife	Short	9	28	14	51
	Medium	25	51	28	104
	Tall	12	20	18	50
		46	99	60	205

Table 2 Assortative mating. Data based on 1000 to 1050 cases of husband and wife

	Husband’s character	Wife’s character	Correlation and probable error
Direct	Stature	Stature	0.2804 ± 0.0189
	Span	Span	0.1989 ± 0.0204
	Forearm	Forearm	0.1977 ± 0.0205
Cross	Stature	Span	0.1820 ± 0.0201
	Stature	Forearm	0.1403 ± 0.0204
	Span	Stature	0.2033 ± 0.0199
	Span	Forearm	0.1533 ± 0.0203
	Forearm	Stature	0.1784 ± 0.0201
	Forearm	Span	0.1545 ± 0.0203

In addition to the present-day research that continues to provide evidence for positive assortative mating for anthropometric characteristics, considerable evidence is also available for race, socioeconomic status, age, intellectual ability, education, physical attractiveness, occupation, and to a lesser extent, for personality and attitude variables [3]. Among anthropometric characteristics, mate correlations for stature are generally the highest; among intellectual ability characteristics, verbal ability, and among personality variables, extraversion.

It is worth noting that the motivation for measuring assortative mating by Galton, **Pearson**, and their contemporaries was to assess its effect on a characteristic’s phenotypic variance in the population. The question of greatest interest was what would happen to the phenotypic variance of a characteristic, and other characteristics ‘incidentally’ correlated with it, if mate selection occurred on the basis of the characteristic’s perceived value. The general finding of this research was that even with relatively small correlations between mates, the characteristic’s phenotypic variance would increase dramatically among offspring if the correlation was positive and decrease dramatically if the correlation was negative. This was even true for the variance of characteristics moderately associated with the selected characteristic [4].

Although the degree of assortative mating r between the phenotypic values of mated individuals is observable, the genetic consequences depend on the correlation m between the **Genotype** of the mates. To determine the association between r and m , what governs the choice of mates must be known. Mate choice can be based on phenotypic similarity (phenotypic homogamy) or environmental similarity (social homogamy), or both. Phenotypic similarity means that the mates are selected on the basis of their phenotypic values for a characteristic. When mate choice is based on the phenotype, the effect of positive assortative mating is to increase population **additive genetic variance (heritability)**; the effect of negative assortative mating is to decrease it. For example, positive assortative mating’s effect of increasing a characteristic’s heritability is illustrated in Figure 1. In this figure, m is the genetic correlation between mates, b is the path between a parent’s genotype and the gametes produced by the parent, and a is the path between the gametes and the genotype of an offspring. Under conditions of random mating, $m = 0$, and the correlation between either parent and

Figure 1 Correlation between family members under assortative mating; G_F = father genotype; G_M = mother genotype; G_C = child genotype; G_{A_F} = father gametes; G_{A_M} = mother gametes; m = genetic correlation between father and mother; b = the path from father or mother genotype to father or mother gametes; and a = the path from father or mother gametes to child genotype

offspring is $a \times b$. When m is greater than zero, the genetic correlation between a single parent and child, r_{op} , increases by a factor of $(1 + m)$:

$$\begin{aligned} r_{op} &= (ab + abm) \\ &= ab(1 + m). \end{aligned} \quad (1)$$

Thus, the genetic correlation between parent and offspring increases whenever m , the genetic correlation between mates, is nonzero. Further details can be found in [1].

On the other hand, if assortative mating occurs *only* through environmental similarity, such as social class, $m = 0$ and there is effect on the characteristic's heritability. However, in modern times when marriages are less likely to be arranged, it is extremely unlikely that selection is based solely on characteristics of the individuals' environment, without consideration given to phenotypic characteristics. In addition, heritability will still increase if differences on the environmental characteristic are in part due to genetic differences among individuals. For example,

the significant heritability of social class would argue for assortative mating arising from both phenotypic and social homogamy.

Determining the impact of assortative mating on genetic variance is critical when attempting to estimate the heritability of a characteristic. When human twins are used to estimate heritability, assortative mating is assumed to be negligible; if this assumption is not made, assortative mating must be explicitly factored into the estimation of the heritability. Two types of twins exist. Monozygotic (identical) twins result from the splitting of a single, fertilized ovum, and are genetically identical; dizygotic (fraternal) twins result from the fertilization of two separate ova, and are no more genetically alike than full siblings. If heredity influences a characteristic, identical twins (who have identical genotypes) should be more alike than fraternal twins (who share on the average 50% of their genes). If the identical twins are no more alike than fraternal twins, the heritability of the characteristic is essentially zero. If assortative mating is assumed to be negligible, heritability is calculated by subtracting the fraternal twin correlation from the identical twin correlation and doubling the difference. If this assumption is incorrect, the identical twin correlation is unaffected, but the fraternal twin correlation is increased. The result will be that the correlation between fraternal twins will be closer to the correlation between identical twins, thereby spuriously lowering the heritability estimate.

Asymptotic Relative Efficiency

When deciding among estimators or test procedures, one naturally will prefer the estimator or test procedure that requires the least number of observations to ensure it is sufficiently close to the true population value (*see Estimation*). The *asymptotic relative efficiency* (ARE) or Pitman efficiency of an estimation or testing procedure is defined as ‘the limit with increasing sample size of the ratio of the number of observations required for each of two consistent statistical procedures to achieve the same degree of accuracy’ [1, p. 42].

For example, when the observations are drawn from a Normal distribution, the **Hodges-Lehmann estimator** of central location has an ARE of 0.96 relative to the arithmetic mean [2, p. 246]. In the same circumstances, the sign test has an ARE with respect to the t Test of only 0.67. In other words, the sign test requires almost ‘50% more observations than the t Test to achieve the same power’ [2, p. 176].

The ARE and, thus, the appropriate test or estimator strongly depends upon the distribution from which the observations are drawn. For example, the ARE of

the Wilcoxon test with respect to the t Test is 0.95 when the observations are drawn from a Normal distribution, but with distributions that are more heavily weighted in the tails than the Normal, the **Wilcoxon test** could have an ARE with respect to the t of 10 or more [2, p. 176].

It is important, therefore, to have a good idea of the kind of distribution sampled. Further, the ARE summarizes large sample results and may not be a trustworthy guide when sample sizes are only small to moderate. Consequently, albeit ARE is an important factor, it should not be the only one to be considered in selecting an estimator or test procedure.

Attitude Scaling

Introduction

A large part of social psychology focuses on the study of attitudes. As [1] said, ‘The concept of attitude is probably the most distinctive and indispensable concept in contemporary American social psychology’. Although the statement was made in the 1930s, the statement rings true today. Attitude research covers a wide variety of topics, such as the study of job performance or absenteeism in factories and how they relate to the attitudes of the factory workers. Political studies often attempt to explain political behaviors such as voting by the attitude of the voting individual. Marketing researchers often wish to study consumers’ attitudes to predict their behavior [15].

Attitudes are simply one of many hypothetical constructs used in the social sciences. They are not observable, and hence are not easily quantified. If attitudes were easily quantified, studying the relationships between the attitudes and dependent variables of interest becomes simple.

In order to scale attitudes, researchers assume attitudes are a measurable quantity. Thurstone’s 1928 paper ‘Attitudes can be measured’ claims just that. In order to do so, the range of attitudes is generally assumed to lie on a single bipolar continuum, or scale. This underlying scale can represent attitudes such as the *liberal-conservative* scale if politics is being studied, or the *risk willingness* scale if investment strategies are the subject of interest. The number of attitudes one might study is infinite. Some of the more popular studied attitudes include social or political attitudes, prejudices, interpersonal attraction, self-esteem, and personal values [14].

Some recent attitudinal studies using attitude scaling methodologies include the following examples:

- *Attitude measurement applied to smoking cessation.* Noël [35] hypothesizes the existence of a unidimensional latent construct representing the level of change a smoker who is attempting to quit has reached. Noël calls this construct the *change maturity index* of the respondent. The author uses a set of 40 statements representing various levels of maturity of cessation to measure the index. ‘Warnings about health hazards of smoking move me emotionally’, and ‘Instead

of smoking I engage in some physical activity’ are two sample statements from the survey given to the smokers in this study.

- *The inventory of interpersonal problems.* Kim and Pilkonis [26] note that one of the best indicators of personality disorders is chronic difficulties in interpersonal relationships. The Inventory of Interpersonal Problems [IIP; 21] is one instrument suggested for studying interpersonal problems. The IIP consists of 127 statements derived from admission interviews with psychiatric patients. Kim and Pilkonis [26] hypothesize these statements measure five latent attitudes: *interpersonal sensitivity*; *interpersonal ambivalence*; *aggression*; *need for social approval*, and *lack of sociability*.
- *Political agency.* Muhlberger [34] studies a latent construct called *political agency* by constructing a set of eight opinion statements that tap varying levels of political agency. The low end of the political agency construct represents the attitudes of individuals following politics for external reasons [others expect them to follow]. The upper end corresponds to ‘intrinsically valuable’ reasons for following politics.

Assuming the attitude of interest lies on a unidimensional, bipolar scale, attitude scaling techniques estimate the position of individuals on that scale. Scaling is achieved by developing or selecting a number of stimuli, or items, which measure varying levels of the attitude being studied. Thurstone [48] advocates the use of opinions, the verbal expressions of attitude. These items, or opinions, are then presented to the respondents and information is collected using some predetermined mode. Researchers use this information to make inferences about the respondents’ attitudes.

Thurstone Scaling

One of the earliest data collection methods for scaling attitudes is **Thurstone’s Law of Comparative Judgment** [LCJ; 47]. The LCJ, which has its roots in psychophysical scaling, measures the items in the same way that psychophysical techniques scale stimuli such as tones on a physiological scale such as loudness. However, this only locates the items on the scale, and a second stage of measurement is needed to measure respondents.

2 Attitude Scaling

Thurstone's method begins by developing a large number of items, or statements, that represent particular attitudes toward the topic of study (e.g., politics; education). Once the set of items is constructed, the items are presented to a group of judges who sort the items. After the items have been scaled from the sorting data, they can be administered to new respondents in a second, separate data collection stage.

Stage One: Locating Items

Method of Paired Comparisons. In the method of paired comparison each of J survey items is paired with each of the other items for a total of $\binom{J}{2}$ item pairs and judges are asked which of the two items in each of the $\binom{J}{2}$ item pairs is located higher on the attitude scale. For example, scaling 10 former US Presidents on the liberalism-conservatism scale would be accomplished by asking the judges to examine each of the $\binom{10}{2} = 45$ pairs of presidents and determine which was more conservative. For example judges might be asked: 'Which US President had the more conservative social policy: Reagan or Clinton'? The judges' attitudes should not affect their responses in any way.

The assumption central to Thurstone's theory is that each survey item produces a psychological sensation in each judge. The sensation is assumed to follow a normal distribution with mean located at the location of the item on the attitude scale. If the psychological sensation produced by item j is larger than the sensation produced by item k for a particular judge, that judge would determine item j is located above item k .

Under Thurstone's Case V Model, for example, the probability that a judge rates item j above item k is represented by $\Phi(\beta_j - \beta_k)$, where Φ is the standard normal cumulative distribution function, and β_j and β_k are the locations of items j and k respectively. Therefore, by using the $J \times J$ matrix, where element (j, k) is the proportion of judges rating item j above item k , the locations of the items are estimated. Mosteller [33] develops a goodness-of-fit statistic for this scaling method.

A similar method for locating items was suggested by [9] and [29]. Their treatment of the paired comparison problem assumes that the probability of choosing item j over item k follows $\Psi(\beta_j - \beta_k)$ where Ψ is the *expit*, or inverse logit function

$(\exp(\cdot)/1 + \exp(\cdot))$. This model for paired comparisons is called the **Bradley-Terry model**. A review of the extensions of paired comparisons models is presented in [8].

The drawback of the paired comparisons item scaling method is that it requires a huge number of comparisons. For example locating the last forty presidents on the liberalism-conservatism scale would require each judge to make $\binom{40}{2} = 780$ paired comparisons.

Method of Equal-appearing Intervals. Because the method of paired comparisons requires so many judgments, Thurstone [49] developed the method of equal-appearing intervals. In this method the judges are asked to separate the items into some fixed number of rating intervals according to where the judge believes the items are located on the latent scale. Assuming the rating intervals are of equal width, the intervals are assigned consecutive scores (e.g., 1–11), and the scale value assigned to each survey item is estimated by the mean or median score received by the item.

Method of Successive Intervals. Thurstone considered the method of equal-appearing intervals as a way to approximate the method of paired comparisons. Realizing that the method of equal-appearing intervals and the method of paired comparisons did not yield perfectly linear results, the method of successive intervals was developed. This method also asks judges to sort the items into some number of interval categories. However, the intervals are not assumed to be of equal width. Once the judgment data is collected, interval widths and item locations are estimated from the data.

Stage Two: Locating Respondents

After the survey items have been located on the latent scale according to one of the three procedures discussed above, the items are used to measure the attitudes of the respondents. The procedure is quite simple. A subset of items (from the item pool measured by the judges) is chosen so that the items are more or less uniformly distributed across the latent scale. Respondents receive the items, one at a time, and are asked whether or not they endorse (e.g., like/dislike) each item. Thurstone's

scaling method assumes that respondents endorse only those items that are located near the respondent; this assumption implies a *unimodal* response function. The method then estimates the location of the respondent with the *Thurstone estimator* which is the average or median location of the endorsed items.

To scale respondents on a social liberalism-conservatism attitude scale, a political scientist might ask the respondents: ‘For each of the following Presidents please mark whether you agreed with the President’s social policy (1 = Agree, 0 = Disagree)’. A respondent might disagree because they feel the President’s social policy was too liberal, or because the policy was too conservative. The scale location of a respondent who agreed with the policy of Clinton and Carter, but disagreed with the remaining Presidents, would be estimated by $\tilde{\theta}_1 = (72.0 + 67.0)/2 = 69.5$. Similarly, the scale position of a second respondent who agreed with the policies of Carter, Ford, and Bush would be estimated as $\tilde{\theta}_2 = (67.0 + 39.3 + 32.8)/3 = 46.4$. The first respondent is more liberal than the second respondent.

Unfolding Response Models

Coombs [11] describes a procedure called *unfolding* which simultaneously scales items and subjects on the same linear scale using only Thurstone’s second stage of data collection. The method assumes there exists some range of attitudes around each item such that all respondents within that range necessarily endorse that item; outside of that range the respondents necessarily disagree with that item (see **Multidimensional Unfolding**).

Coombs’s model is an example of an unfolding response model. Unfolding response models assume that the *item response function*, the probability a respondent located at θ_i endorses an item located at β_j , is a unimodal function which reaches a maximum at β_j . Coombs’s model assumes a deterministic response function:

$$P_j(\theta_i) \equiv P\{X_{ij} = 1|\theta_i\} = \begin{cases} 1 & \text{if } \theta \in (\beta_j - \delta_j, \beta_j + \delta_j) \\ 0 & \text{if } \theta \notin (\beta_j - \delta_j, \beta_j + \delta_j) \end{cases} \quad (1)$$

The parameter δ_j is called the *latitude of acceptance* for item j .

By being able to locate items and respondents simultaneously, it became unnecessary to pre-measure the opinions as required by Thurstone’s scaling method. However, Coombs’s deterministic model is quite restrictive because it does not allow any response pattern to contain the triplet $\{1, 0, 1\}$. For example, if former US Presidents Clinton, Carter, Ford, Bush, and Reagan are ordered from most liberal to most conservative, then a person who endorses the social policy of Presidents Ford and Reagan, but not Bush, violates the model.

Since Coombs’s deterministic unfolding response model, a number of probabilistic models have been developed [e.g., 3, 12, 20, 30]. One of the earliest probabilistic unfolding response models used for scaling in attitude studies is the squared logistic model [3]. The model assumes the logit of the item response function is quadratic in the respondent’s location on the attitude scale. Specifically the model assumes $P_j(\theta) = \Psi(-(\theta - \beta_j)^2)$, which reaches a maximum value of $1/2$ when $\theta = \beta_j$.

The squared logistic model is too restrictive for many attitudinal surveys because the maximal endorsement probability is fixed at $1/2$. The PAR-ELLA [20] and the hyperbolic cosine models [4, 51] overcome this limitation by adding another parameter similar to the latitude of acceptance in Coombs’s model [30]. Unfolding response models for polytomous response scales have also been utilized in attitudinal studies [41]. Noël [35], for example, utilizes a polytomous unfolding response model to scale the attitudes of smokers as they approach cessation.

The locations of items and respondents are estimated using one of a number of estimation algorithms for unfolding responses models. These include joint **maximum likelihood** [3, 4], marginal maximum likelihood [20, 51] and **Markov Chain Monte Carlo** techniques [22, 24]. Post [37] develops a non-parametric definition of the unfolding response model which allows for the consistent estimation of the rank order of item locations along the attitude scale [22]. Assuming Post’s nonparametric unfolding model and that the rank order of item locations is known, [22] shows that the Thurstone estimator (i.e., the average location of the endorsed items) does in fact consistently estimate respondents by their attitudes.

Guttman Scaling

Guttman [18] suggests another method for the scaling of respondents. The main difference between Thurstone's scaling method and Guttman's is in the type of questions used to scale the respondents' attitudes. Guttman's key assumption is that individuals necessarily agree with all items located below their own position on the attitude scale and necessarily disagree with all items above.

Unlike Thurstone's scaling assumption, which implies a unimodal response function, Guttman's assumption implies a monotone response function. In fact, the response function can be parameterized as the step function:

$$P_j(\theta) = \begin{cases} 1 & \text{if } \theta > \beta_j \\ 0 & \text{if } \theta \leq \beta_j. \end{cases} \quad (2)$$

So questions that are valid for Thurstone scaling are not for Guttman scaling. For example a question valid for Thurstone scaling, such as, 'Did you agree with President Reagan's social policy'? might be altered to ask, 'Do you feel that President Reagan's social policy was too conservative?' to use in Guttman scaling.

Once a large number of items have been developed judges are utilized to sort the items. The researcher then performs a *scalogram analysis* to select the set of items that are most likely to conform to Guttman's deterministic assumption.

Guttman's deterministic assumption restricts the number of possible response patterns. If all J items in an attitudinal survey are Guttman items, then at most $J + 1$ response patterns should be observed. These $J + 1$ response patterns rank order survey respondents along the attitude scale. Respondents answering 'No' to all items (00...0) are positioned below respondents who endorse the lowest item (10...0), who lie below respondents who endorse the two lowest items (110...0), and so forth.

Goodman's Partially Ordered Items

Goodman [17] calls a set of strictly ordered items, as assumed in Guttman scaling, a *uniform scale* because there is only one order of items. However in some cases, it is not plausible to assume that items are strictly ordered. Assume that two orderings of past US Presidents from most conservative to most liberal are plausible,

Figure 1 An example of a bifurm scale or belief poset

for example, $\text{Reagan} \rightarrow \text{Ford} \rightarrow \text{Bush} \rightarrow \text{Carter}$ and $\text{Reagan} \rightarrow \text{Bush} \rightarrow \text{Ford} \rightarrow \text{Carter}$. Because there are two plausible orderings of the items, Goodman calls the resulting scale a *bifurm scale*. Wiley and Martin [53] represent this *partially ordered set* of beliefs, or belief *poset* as in Figure 1.

Items are only partially ordered (Reagan is less liberal than both Ford and Bush, and Ford and Bush are less liberal than Carter), hence, unlike Guttman scaling, there is no longer a strict ordering of subjects by the response patterns. In particular, subjects with belief state 1100 (i.e., Reagan and Ford are too conservative) and 1010 (i.e., Reagan and Bush are too conservative) cannot be ordered with respect to one another.

In general, if J items make up a bifurm scale, then $J + 2$ response patterns are possible, as compared to $J + 1$ response patterns under Guttman scaling. Although the bifurm scale can be easily generalized to multifurm scales (e.g., trifurm scales), the limitations placed on the response patterns often prove to be restrictive for many applications.

Monotone Item Response Models

Probabilistic *item response theory* models, a class of generalized mixed effect models, surmount the restrictions of Guttman's and Goodman's deterministic models by adding a random component to the model. The **Rasch model** [39], one example of such a model, assumes the logit of the item response function is equal to the difference between the respondent's location and the item's location (i.e., $\log\{P_j(\theta)/(1 - P_j(\theta))\} = \theta - \beta_j$). The normal-ogive model assumes $P_j(\theta) = \Phi(\theta - \beta)$, where $\Phi(\cdot)$ is the normal cumulative distribution function [28]. The Rasch and normal-ogive models have also been generalized to applications where the latent attitude is assumed to be multidimensional ($\theta \in \mathbb{R}^k$) [6, 32, 40].

Respondents and items are located on the attitude scale using some estimation procedure for item response models. These include joint maximum

likelihood, conditional maximum likelihood [50], marginal maximum likelihood, or empirical Bayes [7, 46], and fully Bayesian methods using Markov chain Monte Carlo techniques [23, 36] (*see Markov Chain Monte Carlo and Bayesian Statistics*). With the recent studies of the nonparametric properties of monotone item response models [19, 25, 45], nonparametric estimation procedures have been suggested [13, 38]. In fact [45] shows under minor regularity conditions that the scale scores, found by summing the responses of an individual over all items, consistently estimate the rank order of respondents along the attitude scale.

Likert Scaling & Polytomous Response Functions

Likert scaling [27], like Thurstone and Guttman scaling, uses a panel of expert judges to locate the items on the attitude scale. However, Likert scaling uses a polytomous response scale (e.g., strongly disagree = 0; disagree = 1; neutral = 2; agree = 3; strongly agree = 4) rather than a dichotomous response scale (disagree = 0; agree = 1). Typically an odd number, usually five or seven, response categories are used, with a middle ‘neutral’ or ‘undecided category’; however, the use of an even number of response categories is equally valid.

The central assumption in Likert scaling is that the respondents located high on the attitude scale are more likely to use high response categories than are individuals located on the low end. If the widths of the response categories are constant across items, then the respondents can be rank ordered along the attitude scale by simply summing their responses across all items. Junker [25] describes conditions under which the Likert scale scores consistently estimate the rank order of respondents along the attitude scale.

Classical Likert scale scores can be thought of as a nonparametric procedure for rank ordering the respondents along the attitude scale. Item response theory models offer a parametric alternative. The Rasch and normal-ogive models have been generalized for use with polytomous item responses. The partial credit model [31] generalizes the Rasch model by assuming the adjacent category logits are equal to the difference between the location of the respondent and the location of the item-category on the attitude

scale:

$$P\{X_j = t | X_j \in \{t-1, t\}\} = \theta - \beta_{jt}. \quad (3)$$

The location of item j is the average of the item’s K item-category locations (i.e., $\beta_j = (1/K) \sum \beta_{jt}$). Johnson, Cohen, and Junker [23] use the PCM to study the attitudes of Research and Development directors towards a number of mechanisms for the appropriation of returns on the company’s innovations.

Ranking Methods

Coombs [10] develops an alternative to the procedures of Thurstone, Guttman, and Likert for the location of items and respondents that is based on respondents comparing items. The data collection method, often called an *unfolding* data method, asks the respondents to rank order items according to their preference. To use this procedure to locate past Presidents and respondents on the social liberalism-conservatism scale the researcher could ask respondents to rank order the Presidents according to how much the respondent agreed with the social policy of the Presidents.

Like the scaling methods discussed earlier, Coombs relies on the assumption that both respondents and survey items are located on the same single scale, and hypothesizes that respondents are more likely to endorse items located near their position on the latent scale. Hence subject i prefers item j to item k if and only if $|\theta_i - \beta_j| < |\theta_i - \beta_k|$, where θ_i is the location of individual i on the latent scale and β_j is the location of item j on the latent scale.

Consider the five items labeled A, B, C, D, and E, and a subject located at θ along the attitude scale (Coombs calls this the *J-scale* for *joint* scale) in Figure 2. Imagine a hinge at the location of the respondent’s attitude and *fold* the scale at that point. This folding results in the rank order of the items for that respondent. The subject located at θ would rank order the items (B, A, C, D, E). Coombs refers to the rank orders given by individuals as *I-scales*.

Coombs designed a method for estimating the rank orders of both the survey items and the survey respondents by assuming that no extraneous variation is present. The assumption of error-free data is a

Figure 2 The relationship between items' and a subject's locations and the observed ranking of the items in Coombs' (1950) unfolding model

serious limitation, and it is not surprising that few real data sets can be analyzed using the method Coombs suggests.

A method that is closely related to Coombs's ranking method is the *pairwise preference* method. The method, like the paired comparison item scaling method, pairs each of the J survey items with the other $J - 1$ items, but unlike the paired comparison method the respondents' personal attitudes affect their responses. For each item pair the respondents are asked to select which of the pair of items they prefer. For example, 'Whose social policy did you prefer, Bush's or Reagan's'?

Assuming pairwise preference is error-free, a respondent whose attitude is located at θ_i on the latent scale prefers item j to item k whenever he or she is located below the midpoint of two items (assuming $\beta_j < \beta_k$). Coombs [11] describes a method to construct a complete rank ordering of all J items from the set of $\binom{J}{2}$ pairwise preference comparisons and estimates the rank order of respondents.

Bechtel [5] introduces a stochastic model for the analysis of pairwise preference data that assumes the location of respondents' attitudes are normally distributed along the attitude scale. Sixtl [44] generalizes this model to a model which assumes a general distribution $F(\theta)$ for the locations of respondents on the attitude scale. The probability that a randomly selected respondent prefers item j to item k closes $P(j \text{ preferred to } k) = \int_{-\infty}^{\infty} I\{t < (\beta_j + \beta_k)/2\} dF(t) = F(\beta_j + \beta_k)/2$. Let $\hat{P}(j \text{ to } k)$

denote the sample proportion of respondents who prefer item j to item k . Sixtl estimates the midpoints between survey items with $F^{-1}(\hat{P}(j \text{ to } k))$, and an *ad hoc* procedure is used to estimate the respondents' locations on the attitude scale.

Summary

The early scaling methods of Thurstone, Guttman, Likert, and Coombs give researchers in the behavioral sciences a way to quantify, or measure, the seemingly unmeasurable construct we call attitude. This measure of attitude allowed researchers to examine how behavior varied according to differences in attitudes. However, these techniques are often too restrictive in their applicability. Modern attitude scaling techniques based on item response theory models overcome many of the limitations of the early scaling methods, but that is not to say they cannot be improved upon.

The increasing use of computer-based attitudinal surveys offer a number of ways to improve on the current attitude scaling methodologies. Typically attitudinal surveys have all respondents answering all survey items, but an adaptive survey may prove more powerful. Computerized adaptive assessments which select items that provide the most information about an individual's attitude (or ability) have been used extensively in educational testing [e.g., 52] and will likely receive more attention in attitudinal surveys. Roberts, Yin, and Laughlin, for example, introduce an adaptive procedure for unfolding response models [42].

The attitude scaling methods described here use discrete responses to measure respondents on the attitude scale. Another direction in which attitude scaling may be improved is with the use of continuous response scales. Continuous response scales typically ask respondents to mark their response on a line segment that runs from 'Complete Disagreement' to 'Complete Agreement'. Their response is then recorded as the proportion of the line that lies below the mark. Because a respondent can mark any point on the line, each response will likely contain more information about the attitude being studied than do discrete responses [2].

Continuous response formats are not a new development. In fact Freyd [16] discussed their use before Thurstone's Law of Comparative Judgment, but continuous response scales were once difficult to implement because each response had to be measured

by hand. Modern computer programming languages make continuous response scales more tractable. There are several options available for the analysis of multivariate continuous responses, including **factor analysis**, multivariate regression models (*see Multivariate Multiple Regression*), and generalizations of item response models to continuous response formats [43].

Attrition

Attrition refers to a loss of response from study participants. With measurement attrition, participants fail to complete outcome measures ranging from a single item to all measures. With treatment attrition, participants drop out of treatment regardless of whether they are measured (*see Dropouts in Longitudinal Studies: Methods of Analysis*).

Attrition can be random or systematic. Attrition is problematic for at least three reasons. First, all attrition reduces (*see Power*) to detect a statistically significant result. Second, systematic attrition can reduce the generalizability of results to the population from which the original sample was drawn. Third, systematic differential attrition (e.g., attrition that is correlated with a treatment condition in an experiment) leaves different kinds of participants in one condition versus another, which can bias estimates of treatment effects. For example, Stanton and Shadish [18] found that addicts with the worst prognosis are more likely to withdraw from discussion groups than from family therapy. If a study suggests that addicts respond better to discussion groups than family therapy, it may simply be because the worst addicts stayed in family therapy. Random differential attrition does not cause such a bias, but it can be difficult to establish whether attrition is random.

Shadish, Cook, and Campbell [16] discuss practical options for preventing and minimizing attrition. A key point is that the researcher should avoid measurement attrition even when treatment attrition occurs. A participant who did not receive the assigned treatment can be included in the analysis provided the participant completed the measures; but a participant with measurement attrition cannot be included in the analysis.

Because attrition is a potential threat to estimates of treatment effects in experiments, the researcher should analyze attrition thoroughly to understand the extent of the threat. Such analyses include simple descriptive statistics of the overall attrition rate, attrition rates broken down by group, overall differences between those who completed the study and those who did not, differences between those who completed the study and those who did not broken down by group, and differences between those who stayed in treatment and those who stayed in the control [7]. More detailed analyses examining whether different

groups or measures have different patterns of attrition may be undertaken with computer programs such as [19] and [11].

Alternatively, the researcher can try to compensate for attrition when estimating effects. The two general approaches are to estimate effects by imputing values for the **missing data** and to estimate effects without directly imputing missing data (*see Dropouts in Longitudinal Studies: Methods of Analysis; Missing Data*). Several approaches to imputing missing data exist [6, 13, 9, 10] (*see* [4] and [14] for accessible overviews). The simplest and least satisfactory approach is mean substitution; the best approach is usually **multiple imputation** with **maximum likelihood estimation**. *See* [5] for a review of computer programs that offer multiple imputation **Maximum Likelihood Estimation**.

When estimating effects without imputing missing data, multigroup **structural equation modeling** approaches may be useful [1–3, 12]. Other methods come from economists and involve modeling the dropout process itself (e.g., [8], and [20]). *See* [16] for a more detailed review of approaches to accounting for attrition when estimating effects. Regardless of whether imputing missing data or not, the researcher will generally want to conduct a variety of analyses under different assumptions about the nature of attrition and offer a range of estimates of effect (e.g., [15]). This can result in sets of treatment estimates under different assumptions that can be made to bracket the true effect under some conditions [17].

Average Deviation

The average deviation (AD) is a reasonably robust measure of scale, usually defined as

$$AD = \frac{\sum |X_i - m|}{n}, \quad (1)$$

where m is some measure of location, usually the mean, but occasionally the median. As defined, the AD is simply the average distance of observations from the center of the distribution. Taking deviations about the median rather than the mean minimizes AD.

The average deviation is often referred to as the mean absolute deviation and abbreviated M. A. D., but that notation is best used to refer to the **median absolute deviation**.

For a normally distributed variable, the average deviation is equal to 0.7979 times the standard deviation (SD). (For distributions of the same shape, the two estimators are always linearly related.) The AD becomes increasingly smaller than the standard deviation for distributions with thicker tails. This is due to the fact that the standard deviation is based on squared deviations, which are disproportionately influenced by tail values.

We often measure the relative qualities of two estimators in terms of their **asymptotic relative efficiency**, which is the ratio of the variances of those estimators over repeated sampling. For a normal distribution, the relative efficiency of the AD in comparison with the sample standard deviation is given by

$$\text{Relative efficiency} = \frac{\text{variance}(SD)}{\text{variance}(AD)} = 0.88 \quad (2)$$

This can be interpreted to mean that you would need to base your estimate of scale using AD as your estimator on 100 cases to have the same standard

error as a standard deviation based on 88 cases. In this case, the standard deviation is 12% more efficient. However, that advantage of the SD over the AD quickly disappears for distributions with more observations in the tails.

Tukey [2] illustrated this for a mixture of samples from two normal distributions with equal means; one distribution with $\sigma = 1.0$ and the other with $\sigma = 3.0$. (You might think of the latter as a distribution of careless responses.) The composite is called a *contaminated distribution*, a type of **finite mixture distribution**. When 99% of the observations were drawn from the first distribution and 1% were drawn from the second (and were not necessarily outliers), the relative efficiency of AD relative to SD jumped from 0.88 for the normal distribution to 1.44 for the contaminated distribution. In other words, the AD was nearly 50% more efficient than the SD for even a slightly contaminated distribution. And this was in a situation in which you would need many thousands of observations for the differences in the two distributions to be obvious to the eye. With only two observations out of 1000 drawn from the ‘contaminating’ distribution, the AD and SD were equally efficient. Tukey long advocated the use of what he called robust statistics, and had relatively little regard for the variance and standard deviation as estimators for data from most research studies [1].

Axes in Multivariate Analysis

Right from the start of development of the topic, multivariate analysis has been closely associated with multidimensional geometry. In one of the pioneering papers, **Pearson** [3] took a geometrical standpoint, using the representation of p variables measured on a sample of n objects as a set of n points in p -dimensional space, and went on to introduce **principal component analysis** as a technique for successively identifying the r -dimensional subspaces of closest fit to these points for $r = 1, 2, \dots, p-1$. This technique is now a cornerstone of descriptive multivariate analysis, and the corresponding geometrical representation of the data is at the heart of many other analytical techniques.

So let us suppose that the p variables $X_1, X_2, \dots, X_p$ have been measured on n sample individuals, and that $\mathbf{x}_i^t = (x_{i1}, x_{i2}, \dots, x_{ip})$ is the vector of P values observed on the i th individual for $i = 1, 2, \dots, n$ (vectors conventionally being interpreted as *column* vectors, hence the transpose superscript ‘t’ when the vector is written as a row). Moreover, we need to assume that all variables are *quantitative*. Then, the above representation of the sample as n points in p dimensions is obtained directly by associating each variable X_j with one of a set of p orthogonal axes in this space and assigning the observed value x_i to the point with coordinates $(x_{i1}, x_{i2}, \dots, x_{ip})$ on these axes.

Of course, this geometrical representation is essentially an idealized model, as we can never actually see it when p is greater than three. Hence, the motivation for Pearson in 1901, and for many researchers since then, has been to identify low-dimensional subspaces of the full p -dimensional space into which the data can be projected in order to highlight ‘interesting’ features in such a way that they can be plotted and seen. Now a one-dimensional subspace is just a line in the original space, a two-dimensional subspace can be characterized by any pair of lines at right angles (i.e., orthogonal) to each other, a three-dimensional subspace by any three mutually orthogonal lines, and so on. Thus, the search for an r -dimensional subspace in the original space resolves itself into a search for r mutually orthogonal lines in the space.

Moreover, if we can quantify the aspect of ‘interestingness’ that we wish to capture in the subspace by some numerical index or function, then the problem becomes one of seeking r mutually orthogonal lines that optimize this index or function. The final step is to realize that if the axes of the original space correspond to the variables $X_1, X_2, \dots, X_p$, then multidimensional geometry tells us that any line Y in the space can be expressed as a linear combination $Y = a_1X_1 + a_2X_2 + \dots + a_pX_p$ for suitable values of the coefficients $a_1, a_2, \dots, a_p$. Moreover, if $Z = b_1X_1 + b_2X_2 + \dots + b_pX_p$ is another line in the space, then Y and Z are orthogonal if and only if

$$a_1b_1 + a_2b_2 + \dots + a_pb_p = \sum_{i=1}^p a_ib_i = 0 \quad (1)$$

Thus, when Pearson looked for an r -dimensional subspace ‘closest’ to the original data points, he in effect looked for r mutually orthogonal combinations like Y and Z that defined this subspace. These he called the *principal components* of the data. **Hotelling** subsequently [1] showed that these components were the mutually orthogonal linear combinations of the original variables that maximized the sample variance among all linear combinations, an operationally better criterion to work with. These components can then be treated as the *axes* of the subspace, and an approximate representation of the data is given by plotting the *component scores* against these axes. Since the axes are related to the original variables, it is often possible to interpret them in terms of the substantive application and this will help in any interpretation of the plot of the scores.

As an example, consider a study conducted into differences in texture as perceived in the mouth among 24 meat samples. A panel of trained assessors scored each of the meat samples on a scale of 0–10 for each of 31 descriptors of texture, so that in our notation above we have $n = 24$ and $p = 31$. The resulting data can thus be visualized as 24 points (representing the meat samples) in 31 dimensions. Clearly, this is impossible to represent physically, but if we conduct a principal component analysis of the data we find that the first two components together account for about two-thirds of the total variance among the meat samples that was present in the original 31 variables. Thus, a simple scatter plot of the scores, using components 1 and 2 as axes, will give a good two-dimensional approximation

Figure 1 A scatter plot of the scores for each of 24 meat samples on the first two principal components

to the true 31-dimensional configuration of points. This plot is shown in Figure 1 below. The 24 meat samples were of four types: reformed meats (type 1), sausages (type 2), whole meats (type 3), and beef burgers (type 4). The points in the diagram are labelled by type, and it is immediately evident that whole meats are recognizably different from the other types. While the other three types do show some evidence of systematic differences, there are, nevertheless, considerable overlaps among them. This simple graphical presentation has thus provided some valuable insights into the data.

In recent years, a variety of techniques producing subspaces into which to project the data in order to optimize criteria other than variance has been developed under the general heading of **projection pursuit**, but many of the variants obtain the data projection in a subspace by direct computational means, without the intermediate step of obtaining linear combinations to act as axes. In these cases, therefore, any substantive interpretation has to be based on the plot alone. Other popular techniques such as *canonical variate analysis* (see **Canonical Correlation Analysis**) produce linear combinations but nonorthogonal ones. These are therefore *oblique* axes in the original space, and if used as orthogonal axes against which to plot scores they produce

a deformation of the original space. In the case of canonical variables, such a deformation is justified because it converts **Mahalanobis distance** in the original space into Euclidean distance in the subspace [2], and the latter is more readily interpretable. In some techniques, such as **factor analysis**, the linear combinations are derived implicitly from a statistical model. They can still be viewed as defining axes and subspaces of the original space, but direct projection of points into these subspaces may not necessarily coincide with derived scores (that are often estimated in some way from the model). In any of these cases, projecting the original axes into the subspace produced by the technique will show the inclination of the subspace to the original axes and will help in the interpretation of the data. Such projection of axes into subspaces underlies the ideas of **biplots**.

The above techniques have required quantitative data. Data sets containing qualitative, nominal, or ordinal variables will not permit direct representation as points in space with coordinates given by variable values. It is, nevertheless, possible to construct a representation using techniques such as **multidimensional scaling** or **correspondence analysis**, and then to derive approximating subspaces for this representation. However, such representations no longer associate variables with coordinate axes, so there are no underlying linear combinations of variables to link to the axes in the approximating subspaces.

Bagging

Bagging was introduced by Leo Breiman in 1996 [1] and is an example of a general class of methods called *ensembles*, in which we combine procedures to give greater predictive accuracy. Bagging stands for ‘bootstrap aggregating’ and means that we apply a regression or classification procedure to bootstrap samples from the original data and aggregate the results.

In bagging, we first take a *bootstrap sample* (see **Bootstrap Inference**) from the data by randomly sampling cases *with* replacement, until the bootstrap sample has the same number of cases as the original data. Some of the original cases will not appear in the bootstrap sample. Others will appear once, twice, or even more often.

To bag a **nonlinear regression** procedure, we take many bootstrap samples (a thousand is not uncommon) and fit a regression model to each bootstrap sample. We combine the fitted models by averaging their predicted response values. Figure 1 illustrates bagging a regression tree. In Figure 1(a), we show the data and the underlying function; in Figure 1(b), the result of fitting a single regression tree (see **Tree Models**); in Figure 1(c), the results of fitting regression trees to 10 bootstrap samples; and in Figure 1(d), the average over 100 such trees. Bagging gives a smoother, more accurate fit than the single regression tree.

For classification, we fit a classifier to each bootstrap sample and combine by choosing the most frequently predicted class, which is sometimes called *voting*. For example, if 55% of the fitted classifiers predict ‘class 1’ and the other 45% predict ‘class 2’, the bagged classifier predicts ‘class 1’.

The classification or regression procedure that we apply to each bootstrap sample is called the *base learner*. Breiman [1] suggests that bagging can substantially increase the predictive accuracy of an *unstable* base learner, that is, one for which small changes in the dataset can result in large changes in the predictions. Examples of unstable methods include trees, stepwise regression, and neural nets, all of which are also *strong learners* – methods that perform much better than random guessing. However, bagging can also turn a very inaccurate method

(a so-called *weak learner*) into a highly accurate method, provided the method is sufficiently unstable. To introduce more instability, the base learner itself may incorporate randomness. Dietterich [4] introduced a method in which the base learners are trees with splits chosen at random from amongst the best 20 splits at each node. **Random forests** [2] can be thought of as bagged trees for which nodes are split by randomly selecting a number of variables, and choosing the best split amongst these variables.

There are several other examples of combining random predictors, such as [5, 6], some of which bypass the bootstrap altogether and simply apply the base learner to the entire dataset, relying on the randomness of the base learner. However, the bootstrap has useful by-products because roughly one-third of the observations are omitted from each bootstrap sample. We can use these so-called *out-of-bag* cases to get good estimates of prediction error [2], eliminating the need for formal cross-validation. They also give measures of variable importance; consider randomly permuting the values of a variable in the out-of-bag cases and comparing the resulting prediction error to the original prediction error on the original out-of-bag data. If the variable is important, the prediction error for the permuted data will be much higher; if it is unimportant, it will be relatively unchanged.

For very large problems (thousands of independent variables), bagging can be prohibitively slow, in which case random forests [3] are more suitable. Bagging trees is a special case of random forests, so the methods for interpreting and understanding random forests are also applicable to bagged trees. Another related method is **boosting**.

We illustrate bagging using a dataset from the Cache County Study on Memory in Aging [7]. The dataset comprised 645 participants aged 65 or older for whom a clinical assessment of Alzheimer’s disease was determined by a panel of experts. We included only subjects who were assessed as non-impaired (having no cognitive impairment) (class 1; 465 people) or having only Alzheimer’s disease (class 2; 180 people). The subjects also completed several neuropsychological tests, and our goal was to investigate how well we could predict the presence of Alzheimer’s disease using the neuropsychological test results.

Figure 1 Bagging regression trees

Table 1 LDA, error rate 4.7%

		Predicted class	
		Non-impaired	Alzheimer's
True class	Non-impaired	91	2
	Alzheimer's	4	32

Table 2 Logistic regression, error rate 3.9%

		Predicted class	
		Non-impaired	Alzheimer's
True class	Non-impaired	90	3
	Alzheimer's	2	34

We imputed missing values using the class-wise medians. Then, we divided the data into a training set of 516 subjects and a test set of 129 subjects. Using the R package (see **Software for Statistical Analyses**), we fit linear **discriminant analysis** (LDA),

Table 3 Classification tree, error rate 10.1%

		Predicted class	
		Non-impaired	Alzheimer's
True class	Non-impaired	88	5
	Alzheimer's	8	28

Table 4 Bagged classification tree, error rate 3.1%

		Predicted class	
		Non-impaired	Alzheimer's
True class	Non-impaired	90	3
	Alzheimer's	1	35

logistic regression, classification trees (see **Classification and Regression Trees**), bagged classification trees, boosted classification trees, and random forests to the training set and used the resulting classifiers to predict the disease status for the test set. We found the results in Tables 1–6.

Table 5 Boosted classification tree, error rate 3.1%

		Predicted class	
		Non-impaired	Alzheimer's
True class	Non-impaired	90	3
	Alzheimer's	1	35

Table 6 Random forests, error rate 2.3%

		Predicted class	
		Non-impaired	Alzheimer's
True class	Non-impaired	91	2
	Alzheimer's	1	35

We note that even though an individual classification tree had the worst performance, when such trees were combined using bagging, boosting, or random forests, they produced a classifier that was more accurate than the standard techniques of LDA and logistic regression.

Balanced Incomplete Block Designs

Agricultural scientists investigating the effects of different fertilizers on crop yields, for example, can split a growing area into different regions called *blocks*. Then they divide each block into plots (cells or units) to receive different treatments. By randomizing the assignment of treatments to the different plots, the experimenters reduce or eliminate bias and facilitate the statistical analysis of yields in different plots and blocks. Similarly, experimenters performing repeated measurements designs (*see Repeated Measures Analysis of Variance; Longitudinal Data Analysis*) often use balancing procedures to equalize the contribution of special effects, such as individual differences, upon the average performance under each treatment. For example, they can employ a **Latin square design** in order to have each person serve once on every occasion and once in every treatment. But if it is necessary to limit the number of observations per person, an incomplete design with fewer observations than treatments is employed. The design becomes a *balanced incomplete design* by adding restrictions, which will be described below. This article examines ways to construct or select a balanced incomplete design with a given number of blocks and treatments. It also presents alternative data analysis procedures that are appropriate for such designs.

One formal structure for a BIBD is as follows. Let there be b blocks (or individual persons) forming the rows of a rectangle, k columns in the rectangle (defining cells in a block), and t treatments, each replicated r times. The total number of observations in the design is $N = rt = bk$. There are other constraints: $b \geq t > k$, preventing any block from including every treatment. The design is balanced in that the number of times, λ , that two treatments such as A and C appear in some block is a constant for all possible pairs of treatments. For an observation Y_{ij} in Treatment i and Block j , the basic model for this design is

$$Y_{ij} = \mu + \tau_i + \beta_j + e_{ij}, \quad (1)$$

where μ is the population mean, τ_i is the effect of Treatment i , β_j is the effect of contribution j , and e_{ij} is error for that observation that is distributed as

$N(0, \sigma^2)$. We adopt the convention that

$$\sum_i \tau_j = \sum_j \beta_j = 0. \quad (2)$$

An Example of a BIBD Experiment

John [6] presents a standard analysis of a dishwashing experiment with the dependent variable being the number of plates washed before foam disappeared, discussing it again in [7, pp. 221–234]. The treatments are nine different detergents. A block consists of three different workers, each with a basin in which to wash with a different detergent in the range from A to J omitting I. The response measure is the number of plates washed at a constant speed before the foam from the detergent disappears. The experiment has $t = 9$ treatments, $k = 3$ plots (cells per block), $r = 4$ replications of each treatment, $b = 12$ blocks, and $\lambda = 1$ cases in which each pair of treatments such as A and C appear together in any block. $N = 4(9) = 12(3) = 36$, which is consistent with the fact that with nine treatments there are $t!/(t-2)!2! = 9!/(7!2!) = 36$ possible treatment pairs. There is another relation between λ and other design features: $\lambda(t-1) = r(k-1)$. Table 1(a) presents this design in a compact form together with data to be discussed below. Table 1(b) presents the same information in a display with the rows as treatments and the columns as blocks, which necessitates blank cells for treatment and block combinations that do not appear.

Intrablock and Interblock Information Assessed for the Example Experiment

In a balanced incomplete blocks design, we have two basic choices as to how to compare the effects

Table 1(a) A balanced incomplete block design with twelve blocks and nine treatments (Design and Data from John [6, p. 52])

		BLOCK						
1	A (19)	B (17)	C (11)	7	A(20)	E(26)	J(31)	
2	D (6)	E (26)	F (23)	8	B(16)	F(23)	G(21)

Mean	15.7	18.3	22.7	15.7	20.7	23.0	25.7	20.0	13.3	21.0	17.3	19.7	19.42

of two or more different treatments. First, consider the problem of comparing responses to Treatments A and B in Table 1. The most common **analysis of variance** method assesses the effects of two design features, blocks, and treatments. Block 1 has a score of 19 under A and a score of 17 under B. The difference, +2, can be called an *intra-block comparison*. Because the [6] data set has $\lambda = 1$, there is only one A – B comparison in our research example. Otherwise we could average all such A – B differences in making an intra-block comparison of these two treatments. A comparison of the performance in different blocks allows the comparison of raw averages for the different blocks, regardless of the treatments involved. However, an overall test of intra-block effects in an analysis of variance must extract block effects first and then extract treatment effects adjusted for block effects. This is called an *intra-block analysis*. Equations 3 through 10 below are consistent with [6, p. 52]. Let

$$C = \frac{\left(\sum_i \sum_j Y_{ij} \right)^2}{N}, T_i = \sum_j Y_{ij}, B_j = \sum_i Y_{ij} \quad (3)$$

and

$$Q_i = kT_i - \sum_j n_{ij} B_j. \quad (4)$$

Because $n_{ij} = 1$ rather than 0 only if Treatment i is present in Block j , Q_i adjusts kT_i by subtracting the total of all block totals for all blocks containing Treatment i . The estimated Treatment i effect is

$$\hat{\tau}_i = \frac{Q_i}{t\lambda}, \quad (5)$$

and the adjusted (*adj*) average for that treatment is

$$\bar{Y}_{i(\text{adj})} = \bar{Y} + \hat{\tau}_i. \quad (6)$$

The sum of squares breakdown for an intra-block analysis is as follows.

$$SS_{\text{Total}} = \sum \sum Y_{ij}^2 - C, \quad (7)$$

$$SS_{\text{Blocks}} = \frac{\sum B_j^2}{k} - C, \quad (8)$$

$$SS_{\text{Treatments(adj)}} = \frac{\sum Q_i^2}{\lambda kt}, \quad (9)$$

and

$$SS_{\text{Residual}} = SS_{\text{Total}} - SS_{\text{Blocks}} - SS_{\text{Treatments(adj)}}. \quad (10)$$

The degree of freedom values are

$$df_{\text{Total}} = N - 1, df_{\text{Blocks}} = b - 1,$$

$$df_{\text{Treatments}} = t - 1, \quad \text{and}$$

$$df_{\text{Residual}} = N - t - b + 1, \text{ respectively.}$$

Alternatively, for an interblock analysis, we can find all treatment averages regardless of the blocks in which they are located. Table 1(b) shows these means for our example data. It is intuitive that we need to compute differences such as $\bar{Y}_A - \bar{Y}_B$ and $\bar{Y}_A - \bar{Y}_C$ on the basis of several observations rather than on one for each treatment, thus computing an *interblock comparison* for any two treatments. In practice, we can either proceed with a general method [7, p. 225] of finding a total sum of squares because of regression

and extracting new squares from it as needed, or by computing the values of SS_{Total} and SS_{Residual} from the intrablock analysis and then finding the unadjusted value of the sum of squares for treatments with the obvious formula:

$$SS_{\text{Treatments}} = \frac{\sum T_i^2}{r} - C. \quad (11)$$

and finding the adjusted sum of squares for blocks by subtraction:

$$SS_{\text{Blocks(adj)}} = SS_{\text{Total}} - SS_{\text{Treatments}} - SS_{\text{Residual}}. \quad (12)$$

Table 2 presents three versions of the analysis of variance for the [6] BIBD example, going beyond calculation of mean squares to include F tests not reported earlier. The first two analyses correspond to the two just described. The so-called Type I analyses extract one effect first and then adjust the sum of squares for the next variable by excluding effects of the first. The first example of a Type I analysis is consistent with a previously published [6, p.54] *intrablock analysis*, in which block effects are extracted first followed by the extraction of treatment effects adjusted for block effects. Here treatment effects and block effects both have very small P values ($p < 0.0001$).

The second Type I analysis reverses the order of extracting the sums of squares. Treatment effects are computed first and then block effects adjusted for treatment effects are measured. Therefore, this is an *interblock analysis*. For this analysis, the treatment effects of the P value is very small ($p < 0.0001$), but the adjusted block effects do not even come close to the 0.05 level.

The third analysis in Table 2 is called a *Type II analysis*. Here an adjusted sum of squares is used

from each effect that has been assessed. Accordingly, for treatments and blocks that are the only factors of interest, this analysis is implied by its predecessors using $SS_{\text{Treatments(adj)}}$ from the intrablock analysis and $SS_{\text{Blocks(adj)}}$ from the interblock analysis. All Table 2 entries not previously computed [6] could have been obtained with a hand calculator using the formulas above or simpler ones such as $F = MS_{\text{Effects}}/MS_{\text{Error}}$. Actually, they were calculated using a SAS Proc GLM Type I or II analysis.

The model of (1) assumes that both treatment and block effects are fixed (*see Fixed and Random Effects*). An alternate mixed effects model used in the SAS program just mentioned is

$$Y_{ij} = \mu + \tau_i + b_j + e_{ij}, \quad (13)$$

where the Roman symbol b_j implies that the effect for the j th block is random rather than fixed as with the Greek β_j of (1). This new model assumes that the blocks have been selected at random from a population of blocks. Most authors performing interblock analyses employ the model in (13).

All sums of squares, mean squares, and F statistics obtained with these two models are identical, but expected mean squares for them differ. One reason to consider using an intrablock analysis is that the average mean square in a BIBD is not contaminated by block effects. With an intrablock analysis of the current data using (13), this expected mean square is $\sigma^2 + \text{a function of treatment effects, } \tau_i^2$. In contrast, with an interblock analysis, the expected mean square is $\sigma^2 + 0.75\sigma_b^2 + \text{a function of treatment effects}$. With the latter expected mean square, a significantly large F for treatments might be due to block effects, σ_b^2 , rather than treatment effects. A comparable problem arises in testing block effects in an intrablock analysis, where the expected mean square for blocks is $\sigma^2 + 3\sigma_b^2 + \text{a function of treatment effects}$. If a

4 Balanced Incomplete Block Designs

test for block effects is not of interest to the experimenter, an intrablock analysis is fine – one merely fails to report a test for block effects. However, a Type II analysis usually has the advantage of yielding uncontaminated expected mean squares (and therefore uncontaminated F values) for both treatment and block effects.

Evaluating Differences Between Two Treatment Effects and Other Contrasts of Effects

An overall assessment of treatment effects in the dishwashing experiment [6] can be supplemented by a comparison of the adjusted average numbers of dishes washed with one detergent and some other detergent. Alternatively, one can make more complicated analyses such as comparing the adjusted average of A and B with the adjusted average for C (see **Multiple Comparison Procedures**). Consider a comparison between A and B. From (6), we know how to compute $\bar{Y}_{A(\text{adj})}$ and $\bar{Y}_{B(\text{adj})}$. We need to know the variance (V) and standard error ($s.e.$) of each adjusted treatment mean and of the difference between two independent adjusted means. Knowing from [1, p. 275] that

$$V(\bar{Y}_{i(\text{adj})}) = \frac{k\sigma^2}{\lambda t}, \quad (14)$$

for each treatment is helpful, but we must estimate σ^2 with MS_{Error} from Table 2 and then use the relation

$$V(\bar{Y}_{A(\text{adj})} - \bar{Y}_{B(\text{adj})}) = \frac{2k\sigma^2}{\lambda t}, \quad (15)$$

leading to

$$s.e.(\bar{Y}_{A(\text{adj})} - \bar{Y}_{B(\text{adj})}) = \sqrt{\frac{2k\sigma^2}{\lambda t}}. \quad (16)$$

Now a standard t Test with $df = N - t - b + 1$ is

$$t = \left(\frac{\bar{Y}_{A(\text{adj})} - \bar{Y}_{B(\text{adj})}}{s.e.(\bar{Y}_{A(\text{adj})} - \bar{Y}_{B(\text{adj})})} \right). \quad (17)$$

For the dishwashing experiment, (4–6) and (14–17) yield

$$T_A = 79, \quad T_B = 67,$$

$$B_A = 234, \quad B_B = 221,$$

$$Q_A = 3, \quad Q_B = -20,$$

$$\hat{\tau}_A = 0.333, \quad \hat{\tau}_B = -2.222,$$

$$\bar{Y}_{A(\text{adj})} = 19.75, \quad \bar{Y}_{B(\text{adj})} = 17.19,$$

$$V(\bar{Y}_{A(\text{adj})}) = 0.2733 = V(\bar{Y}_{B(\text{adj})}),$$

$$V(\bar{Y}_{A(\text{adj})} - \bar{Y}_{B(\text{adj})}) = 0.5467,$$

$$\bar{Y}_{A(\text{adj})} - \bar{Y}_{B(\text{adj})} = 2.556,$$

$$s.e.(\bar{Y}_{A(\text{adj})} - \bar{Y}_{B(\text{adj})}) = 0.74,$$

and

$$t = 3.46, \quad (18)$$

with $df = 36 - 9 - 12 + 1 = 16$, so that a two-tailed test has $p < 0.01$. So performance under Detergent A is significantly better than under Detergent B.

More complicated contrast analyses use standard methods, essentially the same as those with means from a one-way analysis of variance. The principal difference in the BIBD case is that means, variances, and standard errors reflect the adjustments given above.

Evaluation of Possible Polynomial Trends in Treatment Effects for BIBD Data

A further analysis [6] of the dishwashing data moved from the usual study of qualitative treatment variations to quantitative treatment variations. The nine detergents studied included a standard detergent (Control), four with a first base detergent with 0 to 3 amounts of an additive, and four with a second base detergent with 0 to 3 amounts of an additive. Eight contrasts among the nine treatments were evaluated: Linear, quadratic, and cubic components for Base 1; linear, quadratic, and cubic components for Base 2; Base 1 versus Base 2; and Control versus Bases 1 and 2 combined. The resulting fixed effects ANOVA found significant linear and quadratic effects of additive amounts for Base 1, significant linear effects of additive amounts for Base 2, significant superiority of Base 2 over Base 1, and significant superiority of Control over the two averages of Base 1 and 2. As expected, the linear effects were increasing the number of plates washed with increasing amounts of additive. Also see [6] for formulas for this contrast analysis. See also [4, Ch. 5] and various sources such

as manuals for statistical computing packages for a general treatment of polynomial fitting and significance testing.

Bayesian Analysis of BIBD Data

Bayesian analysis adds to conventional statistics a set of assumptions about probable outcomes, thus combining observed data and the investigator's expectations about results (*see Bayesian Methods for Categorical Data*). These expectations are summarized in a so-called prior distribution with specific or even very vague indications of a central tendency measure and variability measure related to those beliefs. The prior distribution plus the observed data and classical assumptions about the data are combined to yield a posterior distribution assigning probabilities to parameters of the model. Box and Tiao [2, pp. 396–416] present a Bayesian method of analysis for BIBD data sets originally assumed to satisfy a mixed model for analysis of variance. Beginning with an assumption of a noninformative prior distribution with equal probabilities of all possible σ_b^2 (block effect variance) and σ_e^2 (error variance) values, they prove an equation defining the posterior distribution of the parameters $\tau_i - \bar{\tau}$. This posterior distribution is a product of three factors: (a) a multivariate t distribution centered at the mean of intrablock treatment effects, (b) a multivariate t distribution centered at the mean of interblock treatment effects, and (c) an incomplete beta integral with an upper limit related to the treatment vector of parameters $\tau_i - \bar{\tau}$. Combining the first two factors permits giving a combined estimate of treatment effects simultaneously reflecting intrablock and interblock effects. Applications of approximation procedures are shown in their [2, pp. 415–417]. Their Table 7.4.5 includes numerical results of this initially daunting analysis method as applied to a set of simulated data for a three-treatment, fifteen-block BIBD experiment. Also see [7, pp. 235–238] for a non-Bayesian combination of intrablock and interblock treatment effects.

Youden Squares as a Device for Increasing the Number of Effects Studied in a BIBD Model

A Youden square is a BIBD with the same number of treatments as blocks. One advantage of using

such a design is that it permits (but does not require) the inclusion and assessment of an additional experimental variable with as many values as the number of plots per block. Normally each value of the added (auxiliary) variable occurs exactly once with each value of the main treatment variable. This is an orthogonal relationship between two variables. Box, Hunter, and Hunter [1, p. 260, pp. 276–279] describe the use of a Youden square design in a so-called wear testing experiment, in which a machine simultaneously measures the amount of wear in $k = 4$ different pieces of cloth after an emery paper has been rubbed against each for 1000 revolutions of the machine. The observed wear is the weight loss (number of 1 milligram units) in a given piece of cloth. Their example presumes $t = 7$ kinds of cloth (treatments) and $b = 7$ testing runs (blocks). An added variable, position of the emery paper rubbing a cloth, had four options with each appearing with one of the four cloths of a block. In discussing this experiment, the authors expand (1) above to include an ' α_l ' effect with this general purpose

$$Y_{ij} = \mu + \alpha_l + \tau_i + \beta_j + e_{ij}. \quad (19)$$

In their case, this extra effect is called an $l = 7$ blocks (positions) effect because it is generated by the emery paper positions within blocks. Table 3 combines information from [1, p. 260, p. 277] to display wear, treatments (from A to G), and blocks (position) in each plot of each block in the experiment. In order to facilitate a later analysis in Table 5, I have reordered cells within the different blocks of [1, p. 277] in a nonunique way ensuring that each treatment appears exactly once in each column of Table 3. A Type I analysis of variance [1, p. 279] assesses

Table 3 Design and data from a Youden square experiment with an extra independent variable [1, p. 260, p. 277]

BLOCK	PLOT				Total
	1	2	3	4	
1	B α 627	D β 248	F γ 563	G δ 252	1690
2	A α 344	C β 233	G γ 226	F δ 442	1245
3	C α 251	G β 297	D γ 211	E δ 160	919
4	G α 300	E γ 195	B δ 537	A β 337	1369
5	F α 595	B γ 520	E β 199	C δ 278	1592
6	E α 185	F β 606	A γ 369	D δ 196	1356
7	D α 273	A β 396	C γ 240	B δ 602	1511

6 Balanced Incomplete Block Designs

Table 4 A SAS PROC MIXED analysis of Table 1 BIBD data, extracting only treatment effects (Blocks are random and serve as a control factor.)

Treatments	8	16	Not shown	220.57	<0.001

these effects in the following order: blocks, blocks (positions), and treatments. Compared to a comparable analysis [1, p. 278] without blocks (positions), the authors find identical sums of squares for treatments and blocks as before. This is a consequence of the orthogonality between treatments and blocks (positions) in the wear testing experiment. Because the sum of squares for the residual error is reduced by the amount of the sum of squares for blocks (position), the F for treatments is increased in the expanded analysis.

Modern Mixed Model Analysis of BIBD Data

In the early analysis of variance work, equations like (1) and (13) above were universally employed, using what is called the **generalized linear model** (GLM) regardless of whether random effects other than error were assumed. More modern work such as [9, p. 139] replaces (13), for example, with

$$\mathbf{Y} = \mathbf{X}\mathbf{B} + \mathbf{Z}\mathbf{u} + \mathbf{e}, \quad (20)$$

where $\mathbf{X}$ is a design matrix for fixed effects, $\mathbf{B}$ is a vector of fixed parameters, $\mathbf{Z}$ is the design matrix for random effects, $\mathbf{u}$ is a vector of random elements, and $\mathbf{e}$ is the vector of error elements. The new kind of analysis estimates the size of random effects but does not test them for significance. Thus, random block effects become a covariate used in assessing treatment effects rather than effects to be tested for significance themselves. We believe, like others such as Lunneborg [10], that more attention needs to be given to the question of whether so-called random effects have indeed been randomly drawn from a specific population. Strict justification of using a *mixed model* analysis or even a random or mixed model GLM analysis seems to require an affirmative answer to that question or some indication of the test's robustness to its failure.

Table 4 summarizes a reanalysis of Table 1 dishwashing data using SAS PROC MIXED. Because

blocks are now treated as a random covariate, the only significance test is for treatments, yielding an $F = 220.57$, almost identical to the 225.94 for the comparable interblock analysis test in Table 2.

Using Youden Squares to Examine Period Effects in a BIBD Experiment Using Mixed Models

Psychologists may desire to use a Youden square or other modified BIBDs design permitting an assessment of the effects of additional features, such as occasions (periods, stages, time, or trial number). Accordingly, Table 5 presents a PROC MIXED analysis of the Table 3 wear testing experiment data with Plots 1 through 4 now being interpreted as stages, and blocks (positions) are ignored. This new analysis shows significant ($p < 0.0001$) effects of treatments but not of stages, even at the 0.05 level. The program employed uses the Kenward–Roger degrees of freedom method of PROC MIXED, as described in [8]. Behavioral scientists using repeated measures in Youden squares and other BIBDs also may want to sacrifice the advantages of orthogonality, such as higher efficiency, in order to analyze both period effects and carryover effects (residual effects of prior treatments on current behavior) as is done with other designs [8]. This also permits the selection from a larger number of BIBDs of a given size, which can facilitate use of randomization tests.

Table 5 A SAS PROC MIXED reanalysis of the Table 3 Youden square example data (Assume that plots (columns) are stages whose effects are to be assessed)

	$df_{\text{numerator}}$	$df_{\text{denominator}}$	F	p

Residual	1140.68			

Assessing Treatment Effects in the Light of Observed Covariate Scores

Littell, Milliken, Stroup, and Wolfinger [9, pp. 187–201] provide extended examples of SAS PROC MIXED analysis of BIBD data for which measures of a covariate also are available. Educators also will be interested in their [9, pp. 201–218] PROC MIXED **analyses of covariance** for data from two split-plot experiments on the effectiveness of different teaching methods with years of teacher's experience as a covariate in one study and pupil IQ as a covariate in the other.

Construction of Balanced Incomplete Block Designs

We delayed this topic until now in order to take into account variations of BIBD discussed above.

Finding all possible designs for a given set of b , k , r , t , and λ is a problem in algebraic **combinatorics**. Cox and Reid [3, pp. 72–73] provide a recent summary of some possible designs in the range $k = 2$ to 4, $t = 3$ to 16, $b = 3$ to 35, and $r = 2$ to 10. See also [7, pp. 221–223, pp. 268–287] for theory and an introduction to early and relevant journal articles, as well as [1, pp. 269–275; 5, p. 74, Table XVII].

Randomization of blocks or possibly also of plots in a BIBD is in principle good experimental design practice [3, pp. 79–80, pp. 252–253]. We now consider the number of possible BIBD designs in the case of very small experiments with $t = 3$ treatments, $b = 3$ blocks, and $k = 2$ plots per block, controlling the set from which a random experiment must be selected.

Case 1. Here is a tiny BIBD with three two-treatment blocks containing Treatments A B, B C, and C A, respectively. Clearly there are $3! = 6$ possible permutations of the three blocks independently of position ordering in the blocks themselves. So a reasonable selection of a BIBD of this structure would choose randomly from 6 options.

Case 2. The examples in Case 1 above are also Youden squares because $t = b$. Suppose we have an auxiliary variable for plots in a block like the 'blocks (position)' of Table 3 or the stage number. Let its values be α and β . Given the same structure of $t = b = 3$, $k = 2$, $r = 2$, and $\lambda = 1$ as before, there are three pairs of ordinary letters that must partially

define our three blocks: A B, A C, and B C. With each pair there are two orderings of the Greek letters. So we can have $(A\alpha B\beta)$ or $(A\beta B\alpha)$ for an A B block. If we do not require orthogonality of treatments and the auxiliary variable, there are $2^3 = 8$ orderings of Greek pairs for the three blocks. But the three blocks may be permuted in six ways, yielding a total of 48 possible designs for this specific Youden square example. With this many options for a simple design or, even better with larger designs with many options, random selection of a specific set of t blocks has the further possible advantage of permitting use of randomization theory in significance testing.

Case 3. Let us modify Case 2 to require orthogonality of treatments and the auxiliary variable. With that constraint, there are two canonical Youden squares for the $t = b = 3$, $k = 2$, $r = 2$, and $\lambda = 1$ case: $(A\alpha B\beta, B\alpha C\beta, \text{ and } C\alpha A\beta)$ or $(B\alpha A\beta, C\alpha B\beta, \text{ and } A\alpha C\beta)$. Each canonical set has 6 permutations of its 3 blocks, yielding a total of 12 possible Youden square designs from which to sample.

Miscellaneous Topics: Efficiency and Resolvable Designs

Efficiency relates most clearly to the variance of a contrast such as between two treatment effects, $\tau_A - \tau_B$. The reference variance is the variance between such effects in a complete design such as a two independent groups' t Test or a two-group comparison in a standard randomized block design with every treatment present in every block. Cox and Reid [3, pp. 78–79] define the efficiency factor of a BIBD as:

$$\varepsilon = \frac{t(k-1)}{(t-1)k}, \quad (21)$$

being less than 1 for all incomplete designs with at least $t = 2$ treatments and $t > k$ plots (units) in a block. But ε is not enough to define efficiency. Quite possibly, the error variance of scores for the different units of a block of t units, σ_t^2 , is different from the error variance of scores from a block with k units, σ_k^2 . Therefore, the efficiency of a BIBD compared to an ordinary randomized block design takes into account these variances as well as ε :

$$\text{Efficiency} = \varepsilon \frac{\sigma_t^2}{\sigma_k^2}. \quad (22)$$

8 **Balanced Incomplete Block Designs**

A *resolvable BIBD* is one in which separate complete analyses of each replication of the data are possible, permitting comparison of the r replicates. In each block of the experiment, each treatment appears exactly once. An analysis of variance for a resolvable design may split its sum of squares for blocks into a sum of squares for replicates and a sum of squares for blocks within replicates [3, pp. 73–74; 7, pp. 226–227].

Bar Chart

A bar chart is a graphical display of data that have been classified into a number of categories. Equal-width rectangular bars are used to represent each category, with the heights of the bars being proportional to the observed frequency in the corresponding category. An example is shown in Figure 1 for the age of marriage of a sample of women in Guatemala.

An extension of the simple bar chart is the component bar chart in which particular lengths of each bar are differentiated to represent a number of frequencies associated with each category forming the chart. Shading or color can be used to enhance the display. An example is given in Figure 2; here the numbers of patients in the four categories of a response variable for two treatments (BP and CP) are displayed.

Figure 2 Component bar chart for response to treatment

Data represented by a bar chart could also be shown as a **dot chart** or a **pie chart**. A bar chart is the categorical data counterpart to the **histogram**.

Battery Reduction

Often a researcher is in the position where he has n variables of interest under investigation, but desires to reduce the number for analysis or for later data collection. Specifically, a researcher may desire to select a subset of m variables from the original n variables that reproduce as much of the information as possible, contained in the original n variables. In other words, he may desire to find the subset of m variables which accounts for a large proportion of the variance of the original n variables. For example, if he has a long questionnaire measuring the effect of a given treatment on the day-to-day activities of a certain population of patients, there may be concern about the burden such a questionnaire places upon the patient. So there is a need to try to reduce the size of the questionnaire (or reduce the battery of questions) without substantially reducing the information obtained from the full questionnaire. To accomplish this, he can perform battery reduction using the data collected from patients who completed the full battery of questions at some time in the past.

There are a number of procedures for performing battery reduction. In the following, we illustrate the concept using Gram–Schmidt transformations. Cureton & D’Agostino [1, Chapter 12] contains complete details of this procedure. Also, D’Agostino et al. [2] have developed a macro in SAS that carries out this procedure and is available from ralph@math.bu.edu.

Assume that the n variables on which we would like to perform battery reduction are denoted $X_1, \dots, X_n$. Assume also that these n variables are standardized with mean zero and variance unity. Then the total variance explained by $X_1, \dots, X_n$, is n , the number of variables. To find the subset of m variables which will explain as much as possible the variance of $X_1, \dots, X_n$, we first perform a **principal component analysis** and decide upon the m components to be retained. These are the components that account for the salient variance in the original data set. The SAS [3] procedure PRINCOMP can be used to perform principal components analysis. The SAS [3] procedure FACTOR can also be employed (*see Software for Statistical Analyses*). Both procedures automatically standardize the variables before employing principal components. Note also that the

above-mentioned battery reduction macro created by D’Agostino et al. [2] automatically standardizes the variables and creates these components as part of its battery reduction.

Once m is determined, let $\mathbf{A}$ denote the $n \times m$ matrix in which the columns contain the correlations of $X_i, i = 1, \dots, n$, to the m principal components. Symbolically $\mathbf{A}$ is

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1m} \\ a_{21} & a_{22} & \dots & a_{2m} \\ \vdots & \vdots & & \vdots \\ a_{n1} & a_{n2} & \dots & a_{nm} \end{bmatrix}. \quad (1)$$

The j th column contains the correlations of the original variables X_i to the j th component, and the sum of the squares of all the $a_{ij}, i = 1, \dots, n, j = 1, \dots, m$, of $\mathbf{A}$ equals the amount of the total variance of the original n variables that is explained by the m retained components. We refer to this as *salient variance*. In principal components analysis, $\mathbf{A}$ is referred to as the *initial component matrix*. It is also often referred to as the *initial factor matrix*. The elements of $\mathbf{A}$ are called the *loadings*. The sum of the squares of the loadings of the i th row of $\mathbf{A}$ equals the proportion of variance of $X_i, i = 1, \dots, n$, explained by the m principal components. This is called the communality of X_i , symbolized as h_i^2 .

Now, to find the subset of m variables which explains, as much as possible, the salient variance of the original n variables, we can employ the Gram–Schmidt orthogonal rotations to the $n \times m$ initial component matrix $\mathbf{A}$. The goal of the Gram–Schmidt rotation in battery reduction is to rotate $\mathbf{A}$ into a new $n \times m$ component matrix, where the variable accounting for the largest proportion of the salient variance (call this ‘variable 1’) has a nonzero loading on the first component, but zero loadings on the remaining $m-1$ components; the variable accounting for the largest proportion of residual variance (‘variable 2’), where residual variance is the portion of the salient variance which is not accounted for by the variable 1, has a nonzero loading on the first two components, but zero loadings on the remaining $m-2$ components; the variable accounting for the largest proportion of second-residual variance (‘variable 3’) has a nonzero loading on the first three components, but zero loadings on

2 Battery Reduction

the remaining $m-3$ components, and so on, until the variable accounting for the largest proportion of the $(m-1)$ th residual variance ('variable m ') is found. Variables 1 through m are then the variables which reproduce, as much as possible, the variance retained by the m principal components, and so also the salient variance contained in the original n variables. In the vocabulary of principal components analysis, variable 1 is the first *transformed component*, variable 2 is the second, and so on. To determine how much of the original variance of all n variables is explained by the m transformed components, we simply compute the sum of squares of all the loadings in the final $n \times m$ Gram-Schmidt rotated matrix (this should be close to the sum of squares of the elements of the $n \times m$ initial component matrix $\mathbf{A}$). The following example will illustrate the use of the Gram-Schmidt process in battery reduction.

In the Framingham Heart Study, a 10-question depression scale was administered (so $n = 10$), where the responses were No or Yes to the following (the corresponding name to which each question will hereafter be referred is enclosed in parentheses):

1. I felt everything I did was an effort (EFFORT).
2. My sleep was restless (RESTLESS).
3. I felt depressed (DEPRESS).
4. I was happy (HAPPY).
5. I felt lonely (LONELY).
6. People were unfriendly (UNFRIEND).
7. I enjoyed life (ENJOYLIF).
8. I felt sad (FELTSAD).
9. I felt that people disliked me (DISLIKED).
10. I could not get going (GETGOING).

A Yes was scored as 1 and No as 0 except for questions 4 and 7, where this scoring was reversed so that a score of 1 would indicate depression for all questions.

After performing a principal components analysis on this data, there were three components with variances greater than unity. The variances of these three components were 3.357, 1.290, and 1.022 for a percentage variance explained equal to $100 \times (3.357 + 1.290 + 1.022)/10 = 56.69\%$. Thus, using the Kaiser rule for selecting the number of retained components [1], we set m equal to 3 for this example. The 10×3 initial component matrix $\mathbf{A}$ is in Table 1.

Table 1 Initial component matrix $\mathbf{A}$ for Framingham Heart Study depression questionnaire

	a_1	a_2	a_3	h^2
EFFORT	0.60	0.15	0.41	0.55
RESTLESS	0.39	0.07	0.55	0.46
DEPRESS	0.77	-0.13	-0.10	0.62
HAPPY	0.70	-0.23	-0.06	0.55
LONELY	0.64	-0.23	-0.21	0.51
UNFRIEND	0.35	0.68	-0.33	0.69
ENJOYLIF	0.52	-0.27	-0.27	0.42
FELTSAD	0.71	-0.22	-0.20	0.59
DISLIKED	0.34	0.72	-0.22	0.68
GETGOING	0.58	0.20	0.47	0.60

Note: $h^2 = a_1^2 + a_2^2 + a_3^2$ is the communality.

Now, to use Gram-Schmidt transformations to determine the three *variables* which explain the largest portion of the salient variance from the original 10 variables, we do the following:

1. Find, from $\mathbf{A}$ in Table 1, the variable which explains the largest proportion of salient variance from the original 10 variables. This is the variable UNFRIEND, with a sum of squares of loadings (communality) across the three components equal to $0.35^2 + 0.68^2 + (-0.33)^2 = 0.69$.
2. Take the loadings of UNFRIEND from Table 1 (0.35, 0.68, -0.33) and normalize them (i.e., divide each element by the square root of the sum of the squares of all three elements). This yields the normalized loadings: 0.42, 0.82, -0.40.
3. Create a 3×3 ($m \times m$) matrix $\mathbf{Y}_1$, which, in the Gram-Schmidt process, is given by

$$\mathbf{Y}_1 = \begin{bmatrix} a & b & c \\ k_2 & -ab/k_2 & -ac/k_2 \\ 0 & c/k_2 & -b/k_2 \end{bmatrix}, \quad (2)$$

where $a = 0.42$, $b = 0.82$, $c = -0.40$ (the normalized row of UNFRIEND from $\mathbf{A}$), and $k_2 = (1 - a^2)^{1/2}$. Thus,

$$\mathbf{Y}_1 = \begin{bmatrix} 0.42 & 0.82 & -0.40 \\ 0.91 & -0.38 & 0.18 \\ 0 & -0.44 & -0.90 \end{bmatrix}. \quad (3)$$

4. Calculate $\mathbf{A}\mathbf{Y}_1'$, which is shown in Table 2. Note that, for UNFRIEND, the only nonzero loading

Table 2 $\mathbf{B} = \mathbf{A}\mathbf{Y}'_1$

	b_1	b_2	b_3	res. h^2
EFFORT	0.21	0.56	-0.44	0.51
RESTLESS	0.00	0.43	-0.53	0.47
DEPRESS	0.26	0.73	0.15	0.56
HAPPY	0.13	0.71	0.15	0.52
LONELY	0.16	0.63	0.29	0.48
UNFRIEND	0.84	0.00	0.00	0.00
ENJOYLIF	0.11	0.53	0.36	0.41
FELTSAD	0.20	0.69	0.28	0.55
DISLIKED	0.82	0.00	-0.12	0.01
GETGOING	0.22	0.54	-0.51	0.55

Note: res. h^2 = residual communality = $b_2^2 + b_3^2$.

is on the first component (or first column). This loading is equal to the square root of the sum of squares of the original loadings of UNFRIEND in matrix $\mathbf{A}$ (thus, no 'information' explained by UNFRIEND is lost during the rotation process). For each of the remaining variables in Table 2, we have the following: (i) the squares of the elements in the first column are the portions of the variances of these variables which are accounted for by UNFRIEND; and (ii) the sum of the squares of the elements in the second and third columns is the residual variance (i.e., the variance of the variables not accounted for by UNFRIEND).

5. Find the variable which explains the largest proportion of residual variance (i.e., has the largest residual communality). This is the variable DEPRESS, with a sum of squares of loadings across the last two columns of Table 2 which is equal to $0.73^2 + 0.15^2 = 0.56$.
6. Take the loadings of DEPRESS from Table 2 (0.73, 0.15) and normalize them. This yields the normalized loadings: 0.98, 0.20.
7. Create a 2×2 matrix $\mathbf{Y}_2$, which, in the Gram-Schmidt process, is given by

$$\mathbf{Y}_2 = \begin{bmatrix} b & c \\ c & -b \end{bmatrix}, \quad (4)$$

where $b = 0.98$, $c = 0.20$ (the normalized row of DEPRESS from the last two columns of Table 2). Thus,

$$\mathbf{Y}_2 = \begin{bmatrix} 0.98 & 0.20 \\ 0.20 & -0.98 \end{bmatrix}. \quad (5)$$

Table 3 Final rotated reduced component matrix, $\mathbf{C}$

	c_1	c_2	c_3	h^2
EFFORT	0.21	0.46	0.54	0.55
RESTLESS	0.00	0.31	0.61	0.46
DEPRESS	0.26	0.75	0.00	0.63
HAPPY	0.13	0.73	0.00	0.55
LONELY	0.16	0.68	-0.16	0.51
UNFRIEND	0.84	0.00	0.00	0.70
ENJOYLIF	0.11	0.59	-0.25	0.42
FELTSAD	0.20	0.73	-0.14	0.59
DISLIKED	0.82	-0.02	0.12	0.67
GETGOING	0.22	0.43	0.61	0.60

Note: $h^2 = c_1^2 + c_2^2 + c_3^2$ is the final communality.

8. Postmultiply the last two columns of $\mathbf{A}\mathbf{Y}'_1$ by $\mathbf{Y}'_2$; the result is shown in the last two columns of Table 3. The first column of Table 3 is the first column of $\mathbf{A}\mathbf{Y}'_1$. Together, the three columns are called the rotated reduced component matrix (matrix $\mathbf{C}$ of Table 3).

Note that, for DEPRESS, the loading on the last component (or last column) is zero. The sum of squares of the loadings (the final communality) of DEPRESS in Table 3 is, within rounding error, equal to the square root of the sum of squares of the loadings of DEPRESS in the initial component matrix $\mathbf{A}$ (0.63 vs. 0.62; thus, no 'information' explained by DEPRESS is lost during the rotation process). For the remaining variables in the second column of Table 3, the elements are the portions of the variances of these variables which are accounted for by DEPRESS.

9. The last of the three variables which explains the largest portion of variance in the original 10 variables is GETGOING, since its loading is largest in the last column of Table 3.
10. The sum of squares of all the loadings in Table 3 is approximately equal, within rounding error, to the sum of squares of loadings in $\mathbf{A}$.

Thus the three variables UNFRIEND, DEPRESS, and GETGOING alone retain approximately the same variance that was retained by the first three principal components (which involved all 10 original variables). We have reduced the original battery of 10 questions to three.

The above is presented only as an illustration. It is unlikely that a researcher would need to perform

4 Battery Reduction

a battery reduction on 10 simple items such as those in the example. However, there could be a tremendous gain if the original n was, say, 100 and the number of retained components m was only 10.

Also, the above example focused on finding the m variables that reproduce the variance retained by the principal components. There may be variables with low communalities (thus not related to the other variables). The researcher may want to retain these also. For a discussion of this and presentations of other battery reduction methods, see Cureton & D'Agostino [1, Chapter 12].

Bayes, Thomas

Born: 1701.

Died: April 17, 1761, London, UK.

Thomas Bayes was the son of a nonconformist minister, Joshua Bayes (1671–1746). The date of Bayes's birth is uncertain, but he was probably born in 1701; he died on 17th April 1761 and was buried in Bunhill Fields in the City of London in the same grave as his father. Little is known about his life except that he received an education for the ministry and was, for most of his life, an ordained nonconformist minister in Tunbridge Wells. He was known as a skilful mathematician, but none of his works on mathematics was published in his lifetime. Despite not having published any scientific work, Bayes was elected a Fellow of the Royal Society in 1742. The certificate proposing him for election, dated 8th April 1742, reads

The Revd Thomas Bayes of Tunbridge Wells, Desiring the honour of being selected into this Society,

we propose and recommend him as a Gentleman of known merit, well skilled in Geometry and all parts of Mathematical and Philosophical learning, and every way qualified to be a valuable member of the same.

The certificate is signed by Stanhope, James Burrow, Martin Folkes, Cromwell Mortimer, and John Eames.

Today, Bayes is remembered for a paper that his friend Richard Price claimed to have found among his possessions after his death. It appeared in the Proceedings of the Royal Society in 1763 and has often been reprinted. It is ironic that the work that assured his fame (at least among statisticians), the posthumously published 'Essay toward solving a problem in the doctrine of chance', was ignored by his contemporaries and seems to have little or no impact on the early development of statistics. The work contains the quintessential features of what is now known as Bayes's Theorem (*see* **Bayesian Belief Networks**), a procedure for the appropriate way to combine evidence, which has had and continues to have a major influence in modern statistics.

Bayesian Belief Networks

Bayesian Belief Networks (BBNs) represent knowledge in a directed graph consisting of conditional probabilities (*see Probability: An Introduction*). These probabilities capture both expert judgement and data in a form that makes possible the drawing of valid inferences, which can inform decision making. BBNs describe how knowledge of one event can change the uncertainty associated with related events. In this way, BBNs characterize both causal relationships between events and what can be inferred from diagnostic information.

A brief survey of the laws of probability will aid understanding of BBNs. First to be given is the definition of a conditional probability. The probability of E given F , $p(E|F)$, represents the conditioning of uncertainty about one thing on something else. For example, in scientific inference, $p(H|D)$ could represent your uncertainty about some hypothesis, H , that interests you, given the data, D , you collected in an experiment. In a business application, $p(S|M)$ might represent the probability of a certain level of sales, S , given a successful marketing campaign, M .

Next, the multiplication law of probability shows how probabilities of two events combine to give the probability of the joint event: $p(E \text{ and } F) = p(E) \times p(F|E)$. The probability you will purchase the ticket, event E , and win the lottery, event F , is equal to the probability you will purchase the ticket times the probability of winning the lottery given that you purchased the ticket. In general, if $p(F)$ is judged to be equal to $p(F|E)$, then the two events are considered to be independent; knowledge about E has no effect on uncertainty about F . Then $p(E \text{ and } F) = p(E) \times p(F)$, clearly not the case for this example.

The addition law applies to mutually exclusive events: $p(A \text{ or } B) = p(A) + p(B)$. The probability that team A will win or that team B will win equals the sum of those two individual probabilities, leaving some probability left over for a draw. Next, the probabilities of mutually exclusive and exhaustive events must sum to one, with the probability of the null event (the impossible event) equal to zero.

Combining those laws makes it possible to 'extend the conversation' so that uncertainty about F can include both E and $\sim E$, 'not- E '. Suppose that $\sim E$ represents the probability that your partner purchases a ticket, and that F represents the probability that one of you wins. Then, $p(F) = p(F|E)p(E) + p(F|\sim E)p(\sim E)$.

The mathematics can be shown in the event tree of Figure 1, and in more compact form as a BBN. The tree shows the probabilities on the branches, and because of the conditioning, they are different on the upper and lower branches. The joint probabilities shown at the right of the tree give the product of the two probabilities on the branches. It is the sum of two of those joint probabilities that make up the probability of event F , and of the other two for event $\sim F$, the probability that neither of you wins. The arrow, or arc, connecting the two circles in the belief network indicates that uncertainty about winning is conditional on purchasing the ticket, without explicitly showing the probabilities.

An example shows the application of these laws to BBNs. Assume that the weather is a major contributor to your mood, and consider the event that by noon tomorrow you will be in a grouchy mood. You are uncertain about both your mood and the weather, so a BBN would look like Figure 2.

This compact representation shows the two events, with the arrow representing the conditioning of mood on weather. In BBNs, an arrow often shows the

Figure 1 An event tree with its corresponding BBN

2 Bayesian Belief Networks

Figure 2 A BBN for the influence of weather on mood

Weather		Mood	
Clear	70.0	Pleasant	59.0
Rainy	30.0	Grouchy	41.0

Figure 3 The expanded BBN for the effect of weather on mood

direction of causality, though it can also represent simple relevance, in that knowing about one event reduces uncertainty about the other, even though they are not causally related.

Now assume that weather can be either clear or rainy, and your mood either pleasant or grouchy. It's a moderately dry time of year, but you aren't sure about tomorrow, so you look in an almanac to find that it has been clear on tomorrow's date 70% of the time. Knowing how you react to poor weather, and that other causes can lead to grouchiness, you judge that if the weather is clear, your probability of becoming grouchy is 0.2, but if it is rainy, the probability of grouchiness is 0.9. A more complete representation is shown in Figure 3.

The 70 to 30 repeats the input data, but where does the 59 to 41 come from? The probability of

grouchiness is only 20% sure if the weather is clear, and 90% sure if it rains, so those two probabilities are weighted with the 70 to 30 weather probabilities, and those two products are summed, to give 41% as can be seen in Figure 4.

Your lack of certainty about tomorrow's weather bothers you, so you consult the local weather forecast. You also know the research on the reliability of weather forecasts: in your area when they say 'clear', they are right about 85% of the time, and when they say 'rain', they are right about 75% of the time. Modifying your BBN to include these new data gives the representation shown in Figure 5.

Note that the arrow between Weather and Forecast follows the direction of causality; it is the weather that gives rise to the forecast, not the other way around. The Clear-Rain forecast probabilities of 67 to 33 are the result of applying calculations like those that led to 59 to 41 for mood.

You now check the forecast for tomorrow; it is 'clear'. Changing the probability of clear to 100, which represents that 'clear' was definitely *forecast* rather than 'rain', gives the result in Figure 6.

In light of this forecast, there is now an 88.8% chance of clear tomorrow, and a 27.8% chance of your being in a grouchy mood. The latter probability depends on the weather probabilities, as in Figure 3. But where does the 88.8% come from? Calculating the probabilities for the weather given the forecast requires application of *Bayes's theorem*.

Figure 4 Calculations for the probability of being grouchy for the weather on mood BBN

Forecast		Weather		Mood	
Clear	67.0	Clear	70.0	Pleasant	59.0
Rain	33.0	Rainy	30.0	Grouchy	41.0

Figure 5 The expanded BBN to take account of the weather forecast, with its less-than-perfect reliability

Figure 6 The effect on uncertainty about weather and mood of a ‘clear’ forecast

Let H , a hypothesis, stand for tomorrow’s weather, and D , data, today’s forecast. Bayes’ theorem provides the basis for calculating $p(H|D)$ from the inverse probability, which we know, $p(D|H)$, representing the forecaster’s reliability. Bayes’s theorem is a simple consequence of the above probability laws, with the added recognition that $p(H \text{ and } D)$ must equal $p(D \text{ and } H)$; the order in which H and D are written down makes no difference to their joint probability. Since $p(H \text{ and } D) = p(H|D) \times p(D)$, and $p(D \text{ and } H) = p(D|H) \times p(H)$, then equating the right hand sides of the equations, and rearranging terms, gives Bayes’s theorem:

$$p(H|D) = \frac{p(H) \times p(D|H)}{p(D)} \quad (1)$$

posterior probability = prior probability $\times$ likelihood/probability of the data (see **Bayesian Statistics**).

This result can be shown by ‘flipping’ the original event tree, but Bayes’s theorem is easier to apply in tabular form; see Table 1. Recall that the datum, D , is the forecaster’s prediction today, ‘clear’, and H is the weather that will be realized tomorrow.

Note that D , the forecaster’s ‘clear’, stays the same in the table, while the hypothesis H , next day’s weather, changes, ‘Clear’ in the first row and ‘Rainy’ in the second.

The unreliability of the forecast has increased your original assessment of a 20% chance of grouchiness, if the actual weather is clear, to a 27.8% chance if the forecast is for clear. And by changing the rain

Table 1 Application of Bayes’s theorem after receipt of the forecast ‘clear’

Weather H	Prior $p(H)$	Likelihood $p(D H)$	$P(H) \times p(D H)$	Posterior $P(H D)$
Clear	0.70	0.85	0.595	0.888
Rainy	0.30	0.25	0.075	0.112
Sum = $P(D) = 0.67$				

forecast probability to 100% in the BBN (Figure 7), your chance of grouchy becomes 67.7%, rather less than your original 90%, largely because the forecasts are less reliable for ‘rain’ than they are for ‘clear’.

So, applying the laws of probability, the multiplication and addition laws operating in one direction, and Bayes’s theorem applied in the other direction, allows information to be propagated throughout the network. Suppose, for example, that several days later you recall being in a pleasant mood on the day in question, but can’t remember what the weather was like. Changing the probability of your mood to 100 for ‘pleasant’ in the BBN gives the result shown in Figure 8.

The chance of good weather, while in reality now either zero or 100%, is, for you at this moment, nearly 95%, and the chance of a ‘clear’ forecast the day before, about 82%. In summary, propagating information in the direction of an arrow requires application of the multiplication and addition laws of probability, whereas propagating information against an arrow’s direction invokes Bayes’s theorem.

Figure 7 The effect on uncertainty about weather and mood of a forecast of ‘rain’

Figure 8 Inferences about the weather forecast and subsequently realized weather if a pleasant mood is all that can be recollected for the day of the original inference

The directed graph indicates conditional dependence between events, with missing links in the graph showing independence. Thus, the lack of an arc between forecast and mood shows that the forecast has no impact on your uncertainty about tomorrow's mood. For this simple problem, lack of arcs is trivial, but for complex BBNs consisting of tens or hundreds of nodes, the presence or absence of arcs provides a compact display that allows a user to grasp quickly the structure of the representation. A corresponding event tree could only be displayed on a computer in small sections or on a very large printed surface, and even then the structure would not be easily grasped even with the probabilities displayed on the corresponding branches.

BBNs break the problem down into many relatively simple probability statements, and from these new insights can emerge. It is this property that was recognised early by psychologists, who first developed the fundamental idea of using human expertise to provide the probabilistic inputs [1, 3, 4]. Their studies initially assumed that data were reliable, though not definitive, in pointing to the correct hypothesis, and their systems assumed a single level of inference, from reliable datum to the hypothesis of interest. Studies comparing actual human inferences to the properties of Bayes's theorem led to the surprising conclusion that in general people do not revise their uncertainty as much as is prescribed by Bayesian calculations, a replicable phenomenon called 'conservatism' by the psychologists who discovered it [2, 14].

But real-world data are often unreliable, ambiguous, redundant, or contradictory, so many investigators developed 'cascaded inference' models to accommodate data unreliability and intermediate levels of uncertainty. Examples abound in medical diagnosis: unreliable data (reports of symptoms from patients) may point to physical conditions (signs only observable from tests) that in turn bear on hypotheses of interest (possible disease states). Comparing actual unaided inferences with these cascaded inference models, as reported in a special issue of *Organisational Behavior and Human Performance* [13], showed occasions when people became less certain than Bayesian performance, but other occasions when they were over confident. Sometimes they assumed unreliable data were reliable, and sometimes they ignored intermediate levels of inference. Although another psychologist, David Schum, picked

up these ideas in the 1960s and studied the parallels between legal reasoning and Bayesian inference [16] the agenda for studying human judgement in the face of uncertainty took a new turn with studies of heuristics and biases (*see* **Heuristics: Fast and Frugal; Subjective Probability and Human Judgement**).

The increasing availability of convenient and substantial computer power saw the growth of BBNs from the mid-1980s to the present day. This growth was fuelled by developments in decision analysis and artificial intelligence [8, 11]. It became feasible to apply the technology to very complex networks [5], aided by computer programs that facilitate structuring and entry of data, with the computational complexity left to the computer (the 'mood' model, above, was constructed using Netica [10]). For complex models, special computational algorithms are used, variously developed by Schachter [15], Lauritzen and Spiegelhalter [7], Pearl [12] and Spiegelhalter and Lauritzen [17]. Textbooks by Jensen [6] and Neapolitan [9] provide guidance on how to construct the models.

BBNs are now in widespread use in applications that require consistent reasoning and inference in situations of uncertainty. They are often invisible to a user, as in Microsoft's help and troubleshooting facilities, whose behind-the-scene BBNs calculate which questions would be most likely to reduce uncertainty about a problem. At other times, as in medical diagnostic systems, the probabilistic inferences are displayed. A web search on BBNs already displays tens of thousands of items; these are bound to increase as this form of rational reasoning becomes recognised for its power to capture the knowledge of experienced experts along with hard data, and make this available in a form that aids decision making.

Bayesian Item Response Theory Estimation

The problem of fundamental importance in **item response theory** is the accurate estimation of the parameters that characterize the items and the ability or proficiency levels of examinees. Likelihood-based approaches such as joint, conditional, and marginal maximum likelihood procedures provide reasonable estimates of the item parameters (*see* **Maximum Likelihood Item Response Theory Estimation; Maximum Likelihood Estimation, and Item Response Theory (IRT) Models for Dichotomous Data** for more details). However, more often than not these procedures run into Heywood-type problems and yield estimates in the two- and three-parameter models that are inadmissible in the sense that the estimates of the ability and item parameters fall outside acceptable ranges. Bayesian approaches, by taking into account prior and collateral information, often overcome these problems encountered by likelihood-based approaches (*see* **Bayesian Statistics**).

The Bayesian Framework

At the heart of the Bayesian approach is the well-known Bayes Theorem (*see* **Bayesian Belief Networks**), which provides the well-known relationship among conditional probabilities (*see* **Probability: An Introduction**),

$$\pi(A|B) = \frac{\pi(B|A)\pi(A)}{\pi(B)}, \quad (1)$$

where $\pi(y)$ denotes probability when y is discrete and the probability density function of y when y is continuous. If we denote the vector of unknown parameters γ by A and the observations or Data by B , then,

$$\pi(\gamma|Data) = \frac{\pi(Data|\gamma)\pi(\gamma)}{\pi(Data)}. \quad (2)$$

The expression, $\pi(\gamma|Data)$, is the *posterior density* of γ ; $\pi(Data|\gamma)$ is the joint probability or the probability density of the observations. Once the observations are realized, it ceases to have a probabilistic interpretation and is known as the *likelihood*

function, usually written as $L(Data|\gamma)$; $\pi(\gamma)$ is the *prior density* of the parameters, and is an expression of the information or prior belief a researcher may have about the parameters; $\pi(Data)$ is a function of the observations and hence is a constant, determined so that the posterior density has unit mass, that is, $\pi(Data) = 1 / \int L(Data|\gamma)\pi(\gamma)d\gamma$. Bayes Theorem thus leads to the statement

$$\pi(\gamma|Data) = L(Data|\gamma)\pi(\gamma), \quad (3)$$

that is,

$$Posterior = Likelihood \times Prior. \quad (4)$$

Implicit in the description above is the fact that the parameters are treated as random variables. Thus, in the Bayesian approach, it is meaningful to make probabilistic statements about parameters, for example, determine the probability that a parameter will fall within an interval [3]. This is the point of departure between the Bayesian and the classical or the frequentist approach; in the frequentist approach, the parameters are considered fixed, and hence probabilistic statements about the parameters are meaningless (*see* **Bayesian Statistics; Probability: An Introduction**).

In the Bayesian framework, the posterior density contains all the information about the parameters. Theoretically, a comprehensive description of the parameters can be obtained, for example, the parameters can be described in terms of moments and percentile points. However, in the multiparameter situation, obtaining the moments and percentile points is tedious if not impossible. Consequently, point estimates of the parameters, such as the joint mode or the mean, are usually obtained.

In the context of item response theory, the parameters of interest are the item and ability parameters. In the dichotomous item response models, an item may be characterized by one parameter, the difficulty, b , or two parameters, b, a , the difficulty and discrimination parameters respectively, or three parameters, b, a, c , the difficulty, discrimination, and the pseudo chance-level parameters respectively [5, 6]. In the polytomous case (*see* **Item Response Theory (IRT) Models for Rating Scale Data**), items may be characterized by a set of the threshold/category parameters (the partial credit model) or by threshold/category and discrimination parameters (generalized partial credit model/graded response model) (*see*

2 Bayesian Item Response Theory Estimation

Item Response Theory (IRT) Models for Polytomous Response Data). The examinees are usually characterized by a single ability parameter, θ . The joint posterior density of the item and ability parameters for any one examinee is thus

$$\pi(\xi, \theta|u) = L(u|\xi, \theta)\pi(\xi, \theta), \quad (5)$$

where ξ is the vector of item parameters, θ is the ability parameter for the examinee, and $u = [u_1 u_2 \dots u_n]$ is the vector of responses to n items. The posterior density is determined up to a constant once the likelihood function, $L(u|\xi, \theta)$, is determined and the prior, $\pi(\xi, \theta)$, is specified.

The Likelihood Function

The assumption of local independence in Item Response Theory (IRT) implies that

$$\pi(u|\xi, \theta) = \pi(u_1|\xi, \theta)\pi(u_2|\xi, \theta) \dots \pi(u_n|\xi, \theta), \quad (6)$$

where $\pi(u_j|\xi, \theta)$ is specified by the item response model that is deemed appropriate. In the general case where an item is scored polytomously, with response categories $r_{1j}, r_{2j}, \dots, r_{sj}$ for item j , if we denote the probability of responding in category r_k as $P(u_j = r_{kj}|\xi, \theta) \equiv P_j^{r_{kj}}$ with $r_{kj} = 1$ or 0 , $\sum_k r_{kj} = 1$, and $\sum_k P_j^{r_{kj}} = 1$, then the probability of a response to the item can be expressed as

$$\pi(u_j|\xi, \theta) = P_j^{r_{1j}} P_j^{r_{2j}} \dots P_j^{r_{sj}} = \prod_{k=1}^s P_j^{r_{kj}}. \quad (7)$$

The joint probability of the response vector u is the product of these probabilities, and once the responses are observed, becomes the likelihood

$$L(u|\xi, \theta) = \prod_{j=1}^n \prod_{k=1}^s P_j^{r_{kj}}. \quad (8)$$

With N examinees, the likelihood function is given by

$$L(U|\xi, \theta) = \prod_{i=1}^N \prod_{j=1}^n \prod_{k=1}^s P_j^{r_{kj}}, \quad (9)$$

where U is the response vector of the N examinees on n items, and θ is the vector of ability parameters for the N examinees.

In the dichotomous case with response categories r_1 and r_2 , $r_2 = 1 - r_1$, and $\pi(u_j|\xi, \theta) = P_j^{r_{1j}} Q_j^{1-r_{1j}}$. Thus,

$$\begin{aligned} L(U|\xi, \theta) &= \prod_{i=1}^N \prod_{j=1}^n L(u_j|\xi, \theta_i) \\ &= \prod_{i=1}^N \prod_{j=1}^n P_j^{r_{1j}} Q_j^{1-r_{1j}}. \end{aligned} \quad (10)$$

Prior Specification, Posterior Densities, and Estimation

While the evaluation of the likelihood function is straightforward, the specification of the prior is somewhat complex. In IRT, the prior density, $\pi(\xi, \theta)$, is a statement about the prior belief or information the researcher has about the item and ability parameters. It is assumed *a priori* that the item and ability parameters are independent, that is, $\pi(\xi, \theta) = \pi(\xi)\pi(\theta)$.

Specification of priors for the ability and item parameters may be carried out in a single stage, or a hierarchical procedure may be employed. In the single stage procedure, a distributional form is assumed for ξ and the parameters of the distribution are specified. For example, it may be assumed that the item parameters have a multivariate normal distribution, that is, $\xi|\mu, \Sigma \sim N(\mu, \Sigma)$, and the parameters (μ, Σ) are specified. In the hierarchical procedure, distributional forms are assumed for the parameters (μ, Σ) and the *hyper-parameters* that determine the distribution of (μ, Σ) are specified. In contrast to the single stage approach, the hierarchical approach allows for a degree of uncertainty in specifying priors by expressing prior beliefs in terms of a family of prior distributions. Swaminathan and Gifford [14–16] proposed a hierarchical Bayes procedure for the *joint estimation* of item and ability parameters following the framework provided by Lindley and Smith [8]; Mislevy [9], using the same framework, provided a hierarchical procedure for the *marginal estimation* of item parameters. In the following discussion, only the three-parameter dichotomous item response model is considered since the one- and the two-parameter models are obtained as special cases. The procedures described are easily extended to the polytomous case [11, 12].

In the dichotomous case, when the three-parameter model is assumed, the vector of item parameters

consists of $3n$ parameters: n difficulty parameters, b_j , n discrimination parameters, a_j , and n pseudo chance-level parameters, c_j . While in theory, it is possible to assume a multivariate distribution for the item parameters, specification of the parameters poses some difficulty. To simplify the specification of priors, Swaminathan and Gifford [16] assumed that the sets of item parameters b, a, c are independent. They further assumed that the difficulty parameters b_j are *exchangeable* and that in the first stage, $b_j \sim N(\mu_b, \sigma_b^2)$. In the second stage, they assumed a noninformative prior for μ_b and an inverse chi-square prior with parameters ν_b, λ_b for σ^2 . For the discrimination parameters, they assumed a chi distribution with parameters ν_{aj} and ω_{aj} . Finally, for the c -parameter, they assumed a Beta distribution with parameters s_j and t_j . (see **Catalogue of Probability Density Functions**). The ability parameters are assumed to be exchangeable, and independently and identically distributed normally with mean μ_θ and variance σ_θ^2 . By setting μ_θ and σ_θ^2 as zero and one respectively, the conditions required for identifying the model may be imposed. With these assumptions, the joint posterior density of item and ability parameters after integrating the nuisance parameters, $\nu_b, \sigma_b^2, \mu_\theta, \sigma_\theta^2$, is

$$\begin{aligned} \pi(a, b, c, \theta | \nu_a, \omega_a, s, t, U) &= \int L(U | a, b, c, \theta) \\ &\times \prod_{j=1}^n \pi(a_j | \nu_{aj}, \omega_{aj}) \pi(b_j | \mu_b, \sigma_b^2) \pi(c_j | s_j, t_j) \\ &\times \prod_{i=1}^N \pi(\theta_i | \mu, \sigma^2) d\nu_b d\sigma_b^2 d\mu_\theta d\sigma_\theta^2 \end{aligned} \quad (11)$$

Swaminathan and Gifford [16] provided procedures for specifying the parameters for the prior distributions of the discrimination and the pseudo chance level parameters. Once the parameters of the priors are specified, the posterior density is completely specified up to a constant. These authors then obtained the joint posterior modes of the posterior density as the joint Bayes estimates of the item and ability parameters. Through an empirical study, Gifford and Swaminathan [4] demonstrated that the joint Bayesian procedure offered considerable improvement over the joint maximum likelihood procedure.

In contrast to the approach of Swaminathan and Gifford [16] who assumed that the examinees were

fixed, Mislevy [9], following the approach taken by Bock and Lieberman [1], assumed that the examinees were sampled at random from a population. With this assumption, the marginal joint posterior density of the item parameters is obtained as

$$\pi(\xi | U, \tau) = \int L(U | \xi, \theta) \pi(\theta) \pi(\xi | \tau) d\theta. \quad (12)$$

With the assumption that $\theta \sim N(0, 1)$, the integration is carried out using Gaussian quadrature. The advantage of this marginal Bayesian procedure over the joint Bayesian procedure is that the marginal modes are closer to the marginal means than are the joint modes. It also avoids the problem of improper estimates of structural, that is, item, parameters in the presence of an infinite number of nuisance or incidental ability parameters.

Mislevy [9], rather than specifying priors on the item parameters directly, specified priors on transformed discrimination and pseudo chance-level parameters, that is, on $\alpha_j = \log(a_j)$ and $\gamma_j = \log[c_j/(1 - c_j)]$. With $\beta_j = b_j$, the vector of parameters, $\xi_j = [\alpha_j \beta_j \gamma_j]$, was assumed to have a multivariate normal distribution with mean vector μ_j and variance-covariance matrix Σ_j (see **Catalogue of Probability Density Functions**). At the second stage, it is assumed that μ_j is distributed multivariate normally and that Σ_j has the inverted Wishart distribution, a multivariate form of the inverse chi-square distribution. Although in principle it is possible to specify the parameters of these hyper prior distributions, they present problems in practice since most applied researchers and measurement specialists lack sufficient experience with these distributions. Simplified versions of these prior distributions are obtained by assuming the item parameters are independent. In this case, it may be assumed that α_j is normally distributed, or equivalently that a_j has a lognormal distribution. The parameters of this distribution are more tractable and readily specified. With respect to the pseudo chance-level parameter, computer programs such as BILOG [10] and PARSCALE [12] use the beta prior for the pseudo chance-level parameter, as recommended by Swaminathan and Gifford [16]. A detailed study comparing the joint and the marginal estimation procedures in the case of the two-parameter item response model is provided by Kim et al. [7].

Rigdon and Tsutakawa [13], Tsutakawa [17], [18], and Tsutakawa and Lin [19] have provided alternative marginalized Bayes modal estimation procedures. The procedures suggested by Tsutakawa [18] and Tsutakawa and Lin [19] for specifying priors is basically different from that suggested by Swaminathan and Gifford and Mislevy; Tsutakawa and Lin [19] suggested an ordered bivariate beta distribution for the item response function at two ability levels, while Tsutakawa [18] suggested the ordered Dirichlet prior on the entire item response function. These approaches are promising, but no extensive research has been done to date comparing this approach with other Bayesian approaches.

More recently, the joint estimation procedure outlined above has received considerable attention in terms of **Markov Chain Monte Carlo (MCMC)** procedures. In this approach, observations are sampled from the posterior density, and with these the characteristics of the posterior density, such as the mean, variance, and so on, are approximated. This powerful technique has been widely applied in Bayesian estimation and inference and is receiving considerable attention for parameter estimation in item response models (*see Markov Chain Monte Carlo Item Response Theory Estimation*).

Estimation of Ability Parameters with Known Item Parameters

As mentioned previously, one of the primary purposes of testing is to determine the ability or proficiency level of examinees. The estimation procedure for jointly estimating item and ability parameters may be employed in this case. However, in situations such as computer-adaptive tests, joint estimation may not be possible. The alternative is to employ a two-stage procedure, where in the first stage, item parameters are estimated using the marginal Bayesian or maximum likelihood procedures, and in the second stage, assuming that the item parameters are known, the ability parameters are estimated.

The estimation of ability parameters when item parameters are known is far less complex than the procedure for estimating item parameters or jointly estimating item and ability parameters. Since the examinees are independent, it is possible to estimate

each examinee's ability separately. In this case, if the prior density of θ is taken as normal, then the posterior density of θ is

$$\pi(\theta|u, \xi, \mu, \sigma^2) = L(u|\theta, \xi)\pi(\theta|\mu, \sigma^2) \quad (13)$$

where μ and σ^2 are the mean and variance of the prior distribution of θ . The mode of the posterior density, known as the *maximum a posteriori* (MAP) estimate, may be taken as the point estimate of ability. Alternatively, the mean of the posterior density, the *expected a posteriori* (EAP) estimate [2], defined as

$$\bar{\theta} = \int_{-\infty}^{\infty} \theta \pi(\theta|\xi, \mu, \sigma^2) d\theta, \quad (14)$$

may be taken as the point estimate of θ . The integral given above is readily evaluated using numerical procedures. The variance of the estimate can also be obtained as

$$\text{Var}(\bar{\theta}) = \int_{-\infty}^{\infty} [\theta - \bar{\theta}]^2 \pi(\theta|\xi, \mu, \sigma^2) d\theta. \quad (15)$$

A problem that is noted with the Bayesian estimate of ability is that unless reasonably good prior information is available, the estimates tend to be biased.

In the case of conventional testing where many examinees respond to the same items, a hierarchical Bayesian procedure may prove to be useful. Swaminathan and Gifford [14] applied a two-stage procedure similar to that described earlier to obtain the joint posterior density of the abilities of N examinees. They demonstrated that the hierarchical Bayes procedure, by incorporating collateral information available from the group of examinees, produced more accurate estimates of the ability parameters than maximum likelihood estimates or a single-stage Bayes procedure.

Bayesian Methods for Categorical Data

Introduction

When analyzing data, it is often desirable to take into account available prior information about the quantity of interest. The Bayesian approach to statistical inference is based on a subjective interpretation of probability (*see* **Bayesian Statistics; Subjective Probability and Human Judgement**). Given a prior distribution describing our prior beliefs on the value of an unknown quantity (typically a model parameter), Bayes' theorem (*see* **Bayesian Belief Networks**) allows us to update those beliefs in the light of observed data. The resulting posterior distribution then summarizes all the available information about the quantity of interest, conditional on the posited model. Bayesian methods for the analysis of categorical data use the same classes of models as the classical approach. However, Bayesian analyses are often more informative – the posterior distribution of the parameter containing more information than mere point estimates or test statistics – and may provide more natural solutions in certain situations such as those involving sparse data or unidentifiable parameters.

The analysis of categorical data is, to some extent, still dominated by the classical approach under which inferences are mostly based on asymptotic theory. However, as in many other areas of statistical practice, the Bayesian literature has been growing steadily in recent years. This is mainly due to the continuous development of efficient computational tools, which make it possible to deal with more complex problems. Among other things, this has prompted the development of fully Bayesian analysis of more realistic (if problematic) situations such as those involving missing data, censoring, misclassification, measurement errors, and so on.

Here, we review some of the most common Bayesian methods for categorical data. We focus on the analysis of **contingency tables**, but other useful models are also briefly discussed. For ease of exposition, we describe most ideas in terms of two-way contingency tables. After presenting some preliminary material in the next section, in the

section titled 'Some History', we provide a brief historical account of early Bayesian approaches to the analysis of contingency tables. In the section titled 'Bayesian Inference for Multinomial Data', we review a Bayesian conjugate analysis of the multinomial distribution, which is the basis of some simple analyses of contingency tables. Then, in the section titled 'Log-linear and Generalized Linear Models', we describe a more general and widely used approach based on the class of **log-linear models**. We discuss estimation, hypothesis testing, and model selection. Finally, in the section titled 'Specialized Models', we mention other, specialized models and provide suggestions for further reading.

Preliminaries

Consider a two-way contingency table with r rows and c columns, with cell probabilities π_{ij} and observed counts n_{ij} ($i = 1, \dots, r; j = 1, \dots, c$). Let $n_{i+} = \sum_j n_{ij}$, $n_{+j} = \sum_i n_{ij}$ and $N = \sum_i \sum_j n_{ij}$. Three sampling schemes occur in applications:

- *Scheme 1* (multinomial sampling), where only the total N is fixed.
- *Scheme 2* (product-multinomial sampling or stratified sampling), where either the row (n_{i+}) or column (n_{+j}) totals are fixed.
- *Scheme 3*, where both the row or column totals are fixed. For 2×2 tables, this situation is related to Fisher's 'exact test' (*see* **Exact Methods for Categorical Data**) (*see* [8]).

Analogous sampling schemes occur in multi-way contingency tables when some of the various marginal totals are fixed by the experimenter. Scheme 3 is not very common and we shall not be concerned with it in what follows. The methods required for the analysis of data obtained under Scheme 2 are the same as those corresponding Scheme 1, provided independent priors are chosen for the parameters of all the multinomial distributions. This is a common assumption and thus we will be focusing on Scheme 1 without any real loss of generality.

Let $m = rc$ denote the total number of cells in a two-way, $r \times c$ contingency table. We will sometimes find it convenient to arrange both the cell counts and the cell probabilities in an $m \times 1$ vector.

2 Bayesian Methods for Categorical Data

Thus, we will denote by $\tilde{\pi}_l$ and $\tilde{n}_l$ respectively, the probability and observed count for cell l ($l = 1, \dots, m$) and $\boldsymbol{\pi}$ will denote both $(\tilde{\pi}_1, \dots, \tilde{\pi}_m)^T$ and $(\pi_{11}, \dots, \pi_{rc})^T$, with the entries of the latter arranged in lexicographical order. Similarly, $\mathbf{n}$ will denote both $(\tilde{n}_1, \dots, \tilde{n}_m)^T$ and $(n_{11}, \dots, n_{rc})^T$.

Under multinomial sampling, the vector of counts, $\mathbf{n}$, is regarded as an observation from a $(m-1)$ -dimensional multinomial distribution with index $N = \sum_l \tilde{n}_l$ and unknown parameter vector $\boldsymbol{\pi}$:

$$f(\mathbf{n}|\boldsymbol{\pi}, N) = \frac{N!}{\prod_l \tilde{n}_l!} \prod_l \tilde{\pi}_l^{\tilde{n}_l}, \quad (1)$$

where $\tilde{\pi}_l > 0$ and $\sum_l \tilde{\pi}_l = 1$.

Some History

Early accounts of Bayesian analyses for categorical data include [20], in particular, Section 5.11, and [16], [17], [18], and [27].

Suppose that the cell counts $\mathbf{n}$ have a multinomial distribution with density function (1) and that the prior density of $\boldsymbol{\pi}$ is proportional to $\prod_l \tilde{\pi}_l^{-1}$ over the region $\tilde{\pi}_l > 0$, $\sum_l \tilde{\pi}_l = 1$ (this is a limiting case of the Dirichlet distribution and is meant to describe vague prior information; see section titled ‘Bayesian Inference for Multinomial Data’). Write $\mathbf{y} = (\log \tilde{n}_1, \dots, \log \tilde{n}_m)^T$ and $\tilde{\boldsymbol{\phi}} = (\log \tilde{\pi}_1, \dots, \log \tilde{\pi}_m)^T$, and let $\mathbf{C}$ be a $k \times m$ matrix of rank $k < m$ and rows summing to zero. Then Lindley ([27], Theorem 1) showed that, provided the cell counts are not too small, the posterior distribution of the contrasts $\boldsymbol{\phi} = \mathbf{C}\tilde{\boldsymbol{\phi}}$ is given approximately by

$$\boldsymbol{\phi} \sim MVN(\mathbf{C}\mathbf{y}, \mathbf{C}\mathbf{N}^{-1}\mathbf{C}^T), \quad (2)$$

where $\mathbf{N}$ is a diagonal matrix with entries $(\tilde{n}_1, \dots, \tilde{n}_m)$.

This result provides approximate estimates of the ‘log-odds’ $\tilde{\boldsymbol{\phi}}$, or linear functions thereof, but not of the cell probabilities $\boldsymbol{\pi}$. Nevertheless, when testing common hypothesis in two-way contingency tables (such as independence or homogeneity of populations), Lindley found analogies with the classical **analysis of variance** which greatly simplify the analysis. He proposed a Bayesian ‘significance test’ based on highest posterior density credible intervals (see also [18]). Spiegelhalter and Smith [32] discuss an

alternative testing procedure based on Bayes factors (see also [20]).

For three-way contingency tables, the analogy with the analysis of variance is no longer useful, but the analysis can still be carried out at the cost of additional computations.

Good [19] developed a Bayesian approach to testing independence in multiway contingency tables. Unlike Lindley’s, this approach has the advantage that it does not depend on the availability of large samples and so is applicable even when many expected cell frequencies are small. Moreover, this approach allows one to estimate the cell probabilities (see also [16] and [17]). To test for independence, Good proposed the use of Bayes factors where the priors assumed for the nonnull model are mixtures of symmetric Dirichlet distributions (see also [2]).

Bishop et al. [9] consider pseudo-Bayes estimators arising from the use of a two-stage prior distribution, following a suggestion by Good [18]. Such estimators are essentially empirical Bayes estimators (see also [22]). Bishop et al. also provide various asymptotic results concerning the risk of their estimators.

Leonard [23] uses exchangeable normal priors on the components of a set of multivariate logits. He then derives estimators of the cell frequencies from the resulting posterior distributions. In a subsequent paper [24], he also develops estimators of the cell frequencies from several multinomial distributions via two-stage priors (see also [25] and [26]). Albert and Gupta [6] also consider estimation in contingency tables, but use mixtures of Dirichlet distributions as priors. In [7], they discuss certain tailored priors that allow them to incorporate (i) separate prior knowledge about the marginal probabilities and an interaction parameter in 2×2 tables; and (ii) prior beliefs about the similarity of a set of cell probabilities in $r \times 2$ tables with fixed row totals (see also [4]).

Bayesian Inference for Multinomial Data

Conjugate Analysis

The standard conjugate prior for the multinomial parameter $\boldsymbol{\pi}$ in (1) is the Dirichlet distribution, with density function

$$p(\boldsymbol{\pi}|\boldsymbol{\alpha}) = \frac{\Gamma(\alpha_*)}{\prod_l \Gamma(\alpha_l)} \prod_l \tilde{\pi}_l^{\alpha_l-1}, \quad (3)$$

for $\alpha_l > 0$ and $\alpha_* = \sum_l \alpha_l$, where $\Gamma(\cdot)$ is the **gamma function** (see [1]).

This distribution is characterized by a parameter vector $\alpha = (\alpha_1, \dots, \alpha_m)^T$ such that $E(\pi_l) = \alpha_l/\alpha_*$. The value of α_* is interpreted as a ‘hypothetical prior sample size’, and determines the strength of the information contained in the prior: a small α_* implies vague prior information whereas a large α_* suggests strong prior beliefs about π . Owing to the conjugacy property, the corresponding posterior distribution of π is also Dirichlet with parameter $\alpha_n = (\tilde{n}_1 + \alpha_1, \dots, \tilde{n}_m + \alpha_m)^T$. This distribution contains *all* the available information about the cell probabilities π , conditional on the observed counts $\mathbf{n}$.

In the absence of prior information, we would typically use a rather vague prior. One of the most widely used such priors for the multinomial parameter is precisely the Dirichlet distribution with parameter $\alpha = (1/2, \dots, 1/2)$ (see [20]). In practical terms, however, one could argue that the strength of the prior should be measured in relation to the actual observed sample. Keeping in mind the interpretation of α_* as a ‘prior sample size’, the quantity $I = \alpha_*/(N + \alpha_*)$ can be regarded as the proportion of the total information that is contributed by the prior. Thus, a value of α_* yielding $I = 0.01$ would produce a fairly vague prior contributing about 1% of the total information, whereas $I \approx 1$ would imply that the data are completely dominated by the prior. Since $E(\pi_l) = \alpha_l/\alpha_*$, the individual values of the α_i should be chosen according to the prior beliefs concerning $E(\tilde{\pi}_l)$. These may be based on substantive knowledge about the population probabilities or on data from previous studies. In the case of vague prior information ($I \leq 0.05$, say), $\alpha_l = \alpha_*/m$ for all $l = 1, \dots, m$ is a sensible default choice. When $\alpha_* = 1$, this corresponds to the prior proposed by Perks [31] and can be interpreted as a single ‘prior observation’ divided evenly among all the cells in the table.

When analyzing contingency tables, we often wish to provide a table of expected cell probabilities or frequencies that can be used for other purposes such as computing standardized rates. The raw observed counts are usually not satisfactory for this purpose, for example, when the table has many cells and/or when few observations are available. In such cases, Bayesian estimators based on posterior expectations

$$E(\tilde{\pi}_l|\mathbf{n}) = \frac{\tilde{n}_l + \alpha_l}{N + \alpha_*}, \quad (4)$$

are often used as smoothed expected cell probabilities (see also [9], [13], [6] and [23]).

Testing for Independence

When testing hypothesis concerning the cells probabilities or frequencies in a contingency table, the null hypothesis imposes constraints on the space of possible values of π . In other words, under the null hypothesis, the cell probabilities are given by $\tilde{\pi}_l^0 = h_l(\pi)$ for some functions $h_l(\cdot)$, $l = 1, \dots, m$. As a simple example, consider a $r \times c$ contingency table and a null model which states that the two variables are independent. In this case, it is convenient to use the double-index notation to refer to the individual cell probabilities or counts. Then

$$\pi_{ij}^0 = h_{ij}(\pi) \equiv \pi_{i+} \pi_{+j}, \quad (5)$$

where $\pi_{i+} = \sum_j \pi_{ij}$ and $\pi_{+j} = \sum_i \pi_{ij}$ ($i = 1, \dots, r$; $j = 1, \dots, c$).

Since we have the posterior distribution of π , we can, in principle, calculate the posterior probability of any event involving the cell probabilities π . In particular, the posterior distribution of π induces a posterior distribution on the vector $\pi^0 = (\pi_{11}^0, \dots, \pi_{rc}^0)^T$ of cell probabilities constrained by the null hypothesis.

The null model of independence can be tested on the basis of the posterior distribution of

$$\delta = \delta(\pi) \equiv \sum_l \log \left(\frac{\tilde{\pi}_l}{\tilde{\pi}_l^0} \right) \log(\tilde{\pi}_l). \quad (6)$$

This quantity can be regarded as a Bayesian version of the deviance. It is always nonnegative and is zero if and only if the null model and the saturated model are the same, i.e., if and only if $\pi_l^0 = \pi_l$ for all l .

The marginal posterior distribution of δ is not available in closed form, but it can easily be obtained from that of π using Monte Carlo techniques. In this case, we can generate a sample $\{\pi^{(1)}, \dots, \pi^{(M)}\}$ of size M from the posterior (Dirichlet) distribution of π . Next, we compute $\delta^{(k)} = \delta(\pi^{(k)})$ for each $k = 1, \dots, M$. The resulting values $\{\delta^{(1)}, \dots, \delta^{(M)}\}$ then constitute a sample from the marginal posterior distribution of δ . The accuracy of the Monte Carlo approximation increases with the value of M .

4 Bayesian Methods for Categorical Data

Posterior distributions of δ concentrated around zero support the null model, whereas posterior distributions located away from zero lead to rejection of the null model. Following a suggestion by Lindley [27], we can test the null hypothesis of independence by means of a Bayesian ‘significance test’: reject the null hypothesis if the 95% (say) highest posterior density credible interval for δ does not contain the value zero.

Numerical example. The $3 \times 2 \times 4$ cross-classification in Table 1 shows data previously analyzed in [21]. The data concern a small study of alcohol intake, hypertension, and obesity.

A sample of size $M = 10\,000$ was simulated from the posterior distribution of δ for the null model of

Table 1 Alcohol, hypertension, and obesity data

Obesity	High BP	Alcohol intake (drinks/day)			
		0	1–2	3–5	6+
Low	Yes	5	9	8	10
	No	40	36	33	24
Average	Yes	6	9	11	14
	No	33	23	35	30
High	Yes	9	12	19	19
	No	24	25	28	29

independence of the three variables. Figure 1 (upper-left panel) shows the corresponding histogram. In this case, the posterior distribution of δ is located away

Figure 1 Posterior distribution of δ for various models

from zero, indicating that the model of independence should be rejected.

A similar procedure can be used to perform other analyses of contingency tables, such as tests of homogeneity of populations or even some interaction tests based on simple log-linear model (see section titled ‘Log-linear and Generalized Linear Models’). All we require is (a) the ability to generate large samples from Dirichlet distributions; and (b) standard software capable of producing the estimated expected cell probabilities or cell frequencies under the relevant null model, thus implicitly providing the corresponding functions $h_l(\cdot)$ discussed above.

Other Priors

The Dirichlet distribution is suitable for inputting prior information about the cell probabilities, but it does not allow sufficient structure to be imposed on such probabilities. Alternative classes of prior distribution were mentioned in the section titled ‘Some History’, and, in the next section, we describe yet another alternative which is particularly suitable for log-linear models.

It is often convenient to model multinomial data as observations of independent Poisson variables. This approach leads to valid Bayesian inferences provided that the prior for the Poisson means factors in a particular way (see [27]). This result can be generalized to product-multinomial settings.

Log-linear and Generalized Linear Models

Log-linear models provide a general and useful framework for analyzing multidimensional contingency tables. Consider a two-way contingency table with r rows and c columns. A log-linear model for the cell probabilities has the form

$$\log \pi_{ij} = u_0 + u_{1(i)} + u_{2(j)} + u_{12(ij)},$$

$$i = 1, \dots, r; \quad j = 1, \dots, c; \quad (7)$$

where u_0 is the overall mean, $u_{1(i)}$ and $u_{2(j)}$ represent the main effects of variables 1 and 2 respectively, and $u_{12(ij)}$ represents the interaction between variables 1 and 2 (see, for example, [9]). The number of independent parameters must be equal to the total number of elementary cells in the table, so it is necessary to

impose constraints to reduce the number of independent parameters represented by each u -term. Usually, such constraints take the form $\sum_i u_{1(i)} = \sum_j u_{2(j)} = \sum_i u_{12(ij)} = \sum_j u_{12(ij)} = 0$.

If we consider instead a table of expected counts $\{\mu_{ij}\}$ that sum to the grand total $N = \sum_i \sum_j n_{ij}$, then we have $\mu_{ij} = N\pi_{ij}$ and hence,

$$\log \mu_{ij} = u + u_{1(i)} + u_{2(j)} + u_{12(ij)},$$

$$i = 1, \dots, r; \quad j = 1, \dots, c; \quad (8)$$

where $u = u_0 + \log N$.

As mentioned in the section titled ‘Testing for Independence’, simple models of this type can also be analyzed using the procedure outlined there.

Numerical example (ctd). For the data of Table 1, we now consider the following model with no second-order interaction:

$$\log \mu_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)} + u_{13(ik)} + u_{23(jk)}, \quad (9)$$

where i denotes obesity level, j denotes blood pressure level, and k denotes alcohol intake level.

We simulated a sample of size $M = 10\,000$ from the posterior distribution of δ with the aid of the function `loglin` of the R language and environment for statistical computing (<http://www.R-project.org>). Figure 1 (upper-right panel), shows the corresponding histogram. In this case, the posterior distribution of δ is concentrated around zero, indicating that the model provides a good fit. However, it is possible that a more parsimonious model also fits the data.

Consider, for example, the models

$$\log \mu_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)} + u_{23(jk)}, \quad (10)$$

and

$$\log \mu_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)}. \quad (11)$$

The posterior distribution of δ for each of these models is shown in Figure 1 (lower-left and lower-right panels, respectively). For model (10), the 95% highest posterior density credible interval for δ contains the value zero, whereas, for model (11), this is not

the case. Thus, we reject model (11) and retain model (10), which suggests that alcohol intake and obesity are independently associated with hypertension.

The saturated log-linear model allows $\boldsymbol{\varphi} = (\log \mu_{11}, \dots, \log \mu_{rc})^T$ to take any value on R^{rc} . A nonsaturated model constrains $\boldsymbol{\varphi}$ to lie in some vector subspace of R^{rc} , in which case, we can write

$$\boldsymbol{\varphi} = \mathbf{X}\mathbf{u}, \quad (12)$$

where $\mathbf{X}$ is a ‘design’ matrix with columns containing the values of explanatory variables or the values of dummy variables for main effects and interaction terms, and $\mathbf{u}$ is the corresponding vector of unknown regression coefficients or effects.

Knuiman and Speed [21] discuss a general procedure to incorporate prior information directly into the analysis of log-linear models. In order to incorporate constraints on main effects and interaction parameters, they use a structured multivariate normal prior for all parameters taken collectively, rather than specify univariate normal priors for individual parameters, as in [23] and [22]. A useful feature of this general prior is that it allows separate specification of prior information for different interaction terms. They go on to propose an approximate Bayesian analysis, where the mode and curvature of the posterior density at the mode are used as summary statistics.

Dellaportas and Smith [11] show how a specific **Markov chain Monte Carlo** algorithm – known as the Gibbs sampler – may be implemented to produce exact, fully Bayesian analyses for a large class of generalized linear models, of which the log-linear model with a multivariate normal prior is a special case.

Dellaportas and Forster [10] use reversible jump Markov chain Monte Carlo methods to develop strategies for calculating posterior probabilities of hierarchical log-linear models for high-dimensional contingency tables. The best models are those with highest posterior probability. This approach to model selection is closely related to the use of Bayes factors, but it also takes into account the prior probabilities of all of the models under consideration (see also [3]).

Specialized Models

In this section, we present a selective review of some specialized problems for which modern Bayesian techniques are particularly well suited.

Missing Data: Nonresponse

Park and Brown [28] and Forster and Smith [15] develop Bayesian approaches to modeling nonresponse in categorical data problems. Specifically, the framework they consider concerns contingency tables containing both completely and partially cross-classified data, where one of the variables (Y , say) is a response variable subject to nonignorable nonresponse and the other variables (here collectively denoted by X) are regarded as covariates and are always observed. They then introduce an indicator variable R to represent a dichotomous response mechanism ($R = 1$ and $R = 0$ indicating response and nonresponse respectively). A nonresponse model is defined as a log-linear model for the full array of Y , X , and R . A nonignorable nonresponse model is one that contains a YR interaction term.

Park and Brown [28] show that a small shift of the nonrespondents can result in large changes in the maximum likelihood estimates of the expected cell frequencies. Maximum likelihood estimation is problematic here because boundary solutions can occur, in which case the estimates of the model parameters cannot be uniquely determined. Park and Brown [28] propose a Bayesian method that uses data-dependent priors to provide some information about the extent of nonignorability. The net effect of such priors is the introduction of smoothing constants, which avoid boundary solutions.

Nonidentifiability

Censoring. Standard models for censored categorical data (see **Censored Observations**) are usually nonidentifiable. In order to overcome this problem, the censoring mechanism is typically assumed to be ignorable (noninformative) in that the unknown parameter of the distribution describing the censoring mechanism is unrelated to the parameter of interest (see [12] and the references therein). Paulino and Pereira [29] discuss Bayesian conjugate methods for categorical data under general, informative censoring. In particular, they are concerned with Bayesian estimation of the cell frequencies through posterior expectations. Walker [33] considers maximum *a posteriori* estimates, obtained via an EM algorithm, for a more general class of priors.

Misclassification. Paulino et al. [30] present a fully Bayesian analysis of binomial regression data with a

possibly misclassified response. Their approach can be extended to multinomial settings. They use an informative misclassification model whose parameters turn out to be nonidentifiable. As in the case of censoring, from a Bayesian point of view this is not a serious problem since a suitable proper prior will typically make the parameters identifiable. However, care must be taken since posterior inferences on non-identifiable parameters may be strongly influenced by the prior even for large sample sizes.

Latent Class Analysis. A **latent class model** usually involves a set of observed variables called *manifest variables* and a set of unobservable or unobserved variables called **latent variables**. The most commonly used models of this type are the latent conditionally independence models, which state that all the manifest variables are conditionally independent given the latent variables.

Latent class analysis in two-way contingency tables usually suffers from unidentifiability problems. These can be overcome by using Bayesian techniques in which prior distributions are assumed on the latent parameters.

Evans et al. [14] discuss an adaptive importance sampling approach to the computation of posterior expectations, which are then used as point estimates of the model parameters.

Ordered Categories

Albert and Chib [5] develop exact Bayesian methods for modeling categorical response data using the idea of data augmentation combined with Markov chain Monte Carlo techniques. For example, the probit regression model (see **Probits**) for binary outcomes is assumed to have an underlying normal regression structure on latent continuous data. They generalize this idea to multinomial response models, including the case where the multinomial categories are ordered. In this latter case, the models link the cumulative response probabilities with the linear regression structure.

This approach has a number of advantages, especially in the multinomial setup, where it can be difficult to evaluate the likelihood function. For small samples, this Bayesian approach will usually perform better than traditional maximum likelihood methods, which rely on asymptotic results. Moreover, one can

elaborate the probit model by using suitable mixtures of normal distributions to model the latent data.

Bayesian Statistics

Bruno de Finetti, one of the founders of Bayesian statistics, wrote in his 1974 *Theory of Probability* [3], ‘PROBABILITIES DO NOT EXIST’. He meant that probabilities do not exist as properties of things; instead, they represent an individual’s degree of belief about some unknown event or uncertain quantity. These personal probabilities must, however, obey the laws of probability, such as the multiplication and addition laws that describe how probabilities assigned to individual events combine to describe the uncertainty associated with compound events (*see Probability: Foundations of*). One consequence of those laws is Bayes’s theorem (*see Bayesian Belief Networks*), which shows how probabilities are revised in the light of new information. It is this crucial theorem that brings individual expressions of uncertainty into contact with real-world data, with the result that with sufficient information, two people holding initially very different views will find their final probabilities in near agreement. For a Bayesian, that agreement defines scientific truth.

The idea is to capture one’s uncertainty about an event or uncertain quantity in the form of ‘prior’ probabilities, then gather data, observe the results and summarize them as a special probability known as a *likelihood*, then apply Bayes’s theorem by multiplying the prior by the likelihood, giving a ‘posterior’ probability (the mathematical details are given in the entry on Bayesian belief networks). Put simply,

$$\begin{aligned} &\text{posterior probability} = \text{prior probability} \\ &\quad \times \text{likelihood.} \end{aligned}$$

An example illustrates the approach. Imagine that you wish to know the proportion, π , of people in a defined population who share some characteristic of interest, such as their ability to smell freesias, the South African flower that your spouse, say, experiences as very fragrant, but for you smells faintly or not at all. On the basis of that limited data from two people, you know that π cannot be either zero or one, but it could be any value in between. One way to represent your uncertainty at this point is as the gentle distribution in Figure 1; no probability at $\pi = 0$ or 1, with probabilities increasing away from those values, peaking at 0.5. Now, you ask

many people to smell a bunch of freesias, quitting when you are tired of asking, and find that you have asked 60 people, of whom 45 reported the freesias as very fragrant. Applying Bayes’s theorem results in the peaked distribution of Figure 1. Now, most of your opinion about the proportion of people who can smell freesias falls between about 0.6 and 0.9; prior uncertainty has been transformed by the data into narrower posterior uncertainty. If more people were to be sampled, the current posterior distribution would become the prior, and after the new data were obtained, the new posterior would be even narrower, though it might shift either left or right.

The beginnings of Bayesian statistics date back to 1763 with the publication, posthumously, of a paper by the **Reverend Thomas Bayes** [1], an English nonconformist who recognized the implications of the laws of probability, though he did not explicitly show the theorem that now bears his name. The modern beginnings can be traced to foundations laid by Ramsey [16], de Finetti [2], Good [5], and others, with the first practical procedures developed by Jeffreys [7, 8]. Although **Savage** [17] failed in his attempt to provide a Bayesian justification for classical statistics, he recognized in the second edition that the two approaches are not reconcilable. His book provided a complete axiomatic treatment of both personal probability and utility to encompass decision making, thus extending foundations laid by von Neumann and Morgenstern [20]. These two books stimulated the publication of Schlaifer’s textbooks [18, 19], Raiffa and Schlaifer’s development of Bayesian decision theory [15] and the two-volume textbook by Lindley [11], who was a student of Jeffreys. Phillips provided the first textbook for social scientists [13], with exercises drawn from research reports in psychology, economics, and sociology. Today, many textbooks provide excellent treatments of the topic, with Winkler’s 1972 textbook a particularly good example, now reissued in a second edition [21].

It is worth distinguishing the early reception of Bayesian ideas by the scientific and business communities. Critics in the sciences argued that it was not appropriate to introduce subjectivism into the objective pursuit of truth, and, anyway, prior opinion was too difficult to assess. The business community, on the other hand, welcomed the ability to combine ‘collateral’ information in the prior along with hard data in the likelihood, thereby allowing both experience and data to inform decisions in a

Figure 1 Prior and posterior distributions for the freesias example

formal analysis. In some practical applications, prior probabilities are largely based on hard data, while likelihoods are judged by specialists and experts in the topic at hand. Whatever the source of priors and likelihoods, methods for assessing them are now well developed and routinely applied in many fields [12].

As for the scientists' critique, the thorough examination of the foundations of all statistical inference approaches given by the philosophers Howson and Urbach [6] shows that subjective judgments attend all approaches, Bayesian and classical. For example, the choice of a significance level, the **power** of a test, and Type 1 and Type 2 errors are all judgments in classical methods, though it often appears not to be the case when, for example, social science journals require 0.05 or 0.01 levels of significance for results to be published, thereby relieving the scientist of having to make the judgment.

Bayesian statistics was first introduced to psychologists by Edwards, Lindman, and Savage [4] in their landmark paper that set out two important principles: stable estimation and the likelihood principle. Stable estimation is particularly important for scientific research, for it enables certain properties of prior opinion to justify use of a 'noninformative' prior, that is, a prior that has little control over the posterior distribution, such as a uniform prior. In the freesias example, a uniform prior would be a horizontal line intersecting the y-axis at 1.0. If that were the prior, and the data showed that one person can smell the freesias and the other cannot, then the posterior would be the gentle curve shown as the prior in Figure 1. Stable estimation states that the actual

prior can be ignored if one's prior in the vicinity of the data changes only gently and is not substantially higher elsewhere. That is the case with the freesias example. The proportion of people in the sample who can smell freesias is $45/60 = 0.75$. In the vicinity of 0.75, the actual prior does not change very much (it is mostly about 1.1), and the prior does not show a very much larger amount elsewhere, such as a substantial amount on $\pi = 1.0$, which might be thought appropriate by a flower seller whose clients frequently comment on the strong, sweet smell. Thus, to quote Edwards, Lindman, and Savage, '... far from ignoring prior opinion, stable estimation exploits certain well-defined features of prior opinion and is acceptable only insofar as those features are really present'. For much scientific work, stable estimation justifies use of a uniform prior.

The likelihood principle states that all the information relevant to a statistical inference is contained in the likelihood. For the freesias example, the relevant data are only the number of people who can smell the freesias and the number who cannot. The order in which those data were obtained is not relevant, nor is the rule employed to determine when to stop collecting data. In this case, it was when you became tired of collecting data, a stopping rule that would confound the classical statistician whose significance test requires knowing whether you decided to stop at 60 people, or when 45 'smellers' or 15 'nonsmellers' were obtained.

In most textbooks, much is made of the theory of conjugate distributions, for that greatly simplifies calculations. Again, for the freesias example, the sampling process is judged to be Bernoulli (*see Catalogue of Probability Density Functions*): each 'smeller' is a success, each 'nonsmeller' a failure; the data then consist of s successes and f failures. By the theory of conjugate distributions, if the prior is in the two-parameter Beta family, then with a Bernoulli process generating the data, the posterior is also in the Beta family (*see Catalogue of Probability Density Functions*). The parameters of the posterior Beta are simply the parameters of the prior plus s and f , respectively. For the above example, the prior parameters are 2 and 2, the data are $s = 45$ and $f = 15$, so the posterior parameters are 47 and 17. The entire distribution can be constructed knowing only those two parameters. While Bayesian methods are often more computationally difficult than classical tests, this is no longer a problem with the ready

availability of computers, simulation software, and Bayesian statistical programs (see **Markov Chain Monte Carlo and Bayesian Statistics**).

So how does Bayesian inference compare to classical methods (see **Classical Statistical Inference: Practice versus Presentation**)? The most obvious difference is in the definition of probability. While both approaches agree about the laws of probability, classical methods assume a relative frequency interpretation of probability (see **Probability: An Introduction**). As a consequence, posterior probability distributions play no part in classical methods. The true proportion of people who can smell freesias is a particular, albeit unknown, value, X . There can be no probability about it; either it is X or it is not. Instead, sampling distributions are constructed: if the freesias experiment were repeated over and over, each with, say 60 different people, then the proportion of smellers would vary somewhat, and it is this hypothetical distribution of results that informs the inferences made in classical methods. Sampling distributions enable the construction of confidence intervals, which express the probability that the interval covers the true value of π . The Bayesian also calculates an interval, but as it is based on the posterior distribution, it is called a *credible interval*, and it gives the probability that π lies within the interval. For the freesias example, there is a 99% chance that X lies between 0.59 and 0.86. The **confidence interval** is a probability statement about the interval, while the credible interval is a statement about the uncertain quantity, π , a subtle distinction that often leads the unwary to interpret confidence intervals as if they were credible intervals.

As social scientists know, there are two stages of inference in any empirical investigation, statistical inference concerning the relationship between the data and the statistical hypotheses, and scientific inference, which takes the inference a step beyond the statistical hypotheses to draw conclusions about the scientific hypothesis. A significance level interpreted as if it were a Bayesian inference usually makes little difference to the scientific inferences, which is possibly one reason why social scientists have been slow to take up Bayesian methods.

Hypothesis testing throws up another difference between the approaches. Many significant results in the social science literature establish that a result is not just a chance finding, that the difference on some measure between a treatment and a control group is

‘real’. The Bayesian approach finds the posterior distribution of the difference between the measures, and determines the probability of a positive difference, which is the area of the posterior density function to the right of zero. That probability turns out to be similar to the classical one-tailed significance level, provided that the Bayesian’s prior is noninformative. The Bayesian would report the probability that the difference is positive; if it is greater than 0.95, that would correspond to significance of $p < 0.05$. But the significance level should be interpreted as meaning that there is less than a 5% chance that this result or one more extreme would be obtained if the null hypothesis of no difference were true. Therefore, since this probability is so small, the null hypothesis can be rejected. The Bayesian, on the other hand, asserts that there is better than a 95% chance, based only on the data actually observed, that there is a real difference between treatment and control groups. Thus, the significance level is a probability statement about data, while the Bayesian posterior probability is about the uncertain quantity of interest.

For the freesias example, 60% of the probability density function lies to the left of $\pi = 0.75$, so there is a 60% chance that the proportion π is equal to or less than 0.75. If a single estimate about π were required, the mean of the posterior distribution, $\pi = 0.73$, would be an appropriate figure, slightly different from the sample mean of 0.75 because of the additional prior information.

In comparing Bayesian and classical methods, Pitz [14] showed graphically, cases in which data that led to a classical rejection of a null hypothesis actually provided evidence in favor of the null hypothesis in a Bayesian analysis of the same data, examples of Lindley’s paradox [10]. Lindley proved that as the sample size increases, it is always possible to obtain a significant rejection of a point hypothesis whether it is true or false. This applies for any significance level at all, but only for classical two-tailed tests, which have no interpretation in Bayesian theory.

From the perspective of making decisions, significance levels play no part, which leaves the step between classical statistical inference and decision making bridgeable only by the exercise of unaided judgment (see entries on utility and on strategies of decision making). On the other hand,

Bayesian posterior probabilities or predictive probabilities about uncertain quantities or events are easily accommodated in decision trees, making possible a direct link between inference and decision. While this link may be of no interest to the academic researcher, it is vital in many business applications and for regulatory authorities, where important decisions based on fallible data are made. Indeed, the design of experiments can be very different, as Kadane [9] has demonstrated for the design of clinical trials in pharmaceutical research. This usefulness of Bayesian methods has led to their increasing acceptance over the past few decades, and the early controversies have now largely disappeared.

Bernoulli Family

In his entertaining but irreverent book on the history of mathematics, Eric Temple Bell took the case of the Bernoullis as being clear proof of the heritability of mathematical genius [1]. This remarkable Swiss dynasty produced at least ten mathematicians of note. Because the names, James, John, Nicholas, and Daniel, appear in different generations and also, depending on the account, in Latin, German, French or English forms, identification of individuals is perilous. In this brief account, the English forms of the personal names will be used together with Boyer's [2] system of numbering. Nicholas (1623–1708), a drug merchant but not a mathematician, is the common ancestor and given no numeral but the qualification 'Senior'. Thereafter, numerals I, II, and III are used as the names reappear in successive generations (see Figure 1). One oddity of this system must be noted and that is that the first Nicholas of mathematical note is Nicholas II, his father Nicholas I and grandfather, Nicholas Senior being the only nonmathematicians necessary to include in order to create a connected tree.

Although many of the Bernoullis did work in mathematics of indirect interest to statisticians, three of them, James I, Nicholas II, and Daniel I, did work of direct importance in probability or statistics and they are covered here.

James I

Born: January 6, 1654, in Basle, Switzerland.

Died: August 16, 1705, in Basle, Switzerland.

James (I) Bernoulli was born in Basle in 1654 and studied at the University, graduating in theology in 1676 [9]. In that year, he left to work as a tutor in Geneva and France, returning to Basle in 1681 [6]. From 1677, he started keeping a scientific diary, *Meditationes*, which traces his interests in mathematics. His first publication in mathematics, however, on the subject of the comet of 1680, predicting its return in 1719, was not until in 1681. In 1687, James became professor of mathematics in Basle. With the exception, perhaps, of his younger brother John I (1667–1748), he became the most important early

developer of the infinitesimal calculus in the form proposed by Leibniz, a fact that Leibniz himself recognized in 1694. James's first publication on the subject of probability dates from 1685, but his fame in this field rests primarily on his posthumous work *Ars Conjectandi* (1713), the first 200 pages of which have been described by the distinguished historian of statistics, Anders Hald [6], as a, 'pedagogical masterpiece with a clear formulation of theorems both in abstract form and by means of numerical examples' (p. 225). In the last 30 pages of the book, however, Bernoulli progresses beyond the then current treatment of probability in terms of symmetric chances *a priori* to develop both subjective interpretations of probability and a famous limit theorem in terms of relative frequencies, the first such to be proved in probability theory. In modern terms, we refer to this as the (weak) **law of large numbers** [11].

Nicholas II

Born: October 10, 1687, in Basle, Switzerland.

Died: November 29, 1759, in Basle, Switzerland.

James's nephew, Nicholas (II) Bernoulli is noteworthy as the editor of his uncle's posthumous masterpiece. He also did important work in probability himself, however, although until recently his role in the development of the subject was underestimated [3] and our modern awareness of his importance is largely due to Hald's careful and thorough analysis of his work [6]. Nicholas was born in 1687 in Basle, the year of the publication of Newton's *Philosophiae naturalis principia mathematica* [3]. In 1704, he obtained a master's degree in mathematics and in 1709, aged only 21, a doctorate in jurisprudence for a thesis entitled, *On the Use of the Art of Conjecturing in Law*. This is clearly considerably influenced by his uncle's work and contains many skillful applications of probability to a wide range of insurance and inheritance problems in which the law could be involved. For example, he has a chapter entitled, 'On an absent person presumed dead'. Nicholas was professor at Padua from 1716 to 1719, after which he returned to Basle to hold first a chair in logic (from 1719 according to Hald, but from 1722 according to Csörgő) and then of Roman and canon law. In 1709, he visited Paris and from 1712 to 1713 undertook a grand tour of France, England,

2 Bernoulli Family

Figure 1 A family tree of the mathematical Bernoullis

and the Netherlands, returning via France. These visits enabled him to establish excellent contacts with many of the leading mathematicians of the day and are the origin of his important correspondence with Montmort through which, together with DeMoivre, he contributed to the solution of a problem posed by William Waldegrave. This involves a circular tournament of n players P_1 to P_n of equal skill. P_1 plays P_2 and the winner plays P_3 , the winner playing P_4 and so on. The game stops once a player has beaten every other player in a row. If necessary, P_1 reenters the game once P_n has played and so on. Montmort and DeMoivre had solutions for $n = 3$ and $n = 4$ but Nicholas was able to provide the general solution.

Nicholas also worked on John Arbuthnot's famous significance test. Arbuthnot had data on christenings by sex in London from 1629 to 1710. Male christenings exceeded female ones in every one of the 82 years, and he used this fact to calculate the probability of this occurring by chance as $(1/2)^{82}$. This is equivalent to, but must not necessarily be interpreted as, a one-sided P value. He then argued that this probability was so small that it could not be interpreted as a chance occurrence and, since it was desirable for the regulation of human affairs that there should be an excess of males at birth, was evidence

of divine providence. The official publication date for Arbuthnot's paper was 1710 and Nicholas Bernoulli discussed it with fellows of the Royal Society during his stay in London in 1712. In a letter to Burnet and 'sGravesande, he uses an improved form of his Uncle James's approximation to the tail area of a binomial distribution (see **Catalogue of Probability Density Functions**) to show that Arbuthnot's data are unsurprising if the probability of a male birth is taken to be $18/35$.

Daniel I

Born: February 8, 1700, in Groningen, The Netherlands.

Died: March 17, 1782, in Basle, Switzerland.

Daniel Bernoulli was in his day, one of the most famous scientists in Europe. His early career in mathematics was characterized by bitter disputes with his father John I, also a brilliant mathematician. Daniel was born in Groningen in 1700, but the family soon returned to Basle. In the same way that John's father, Nicholas Senior, had tried to dissuade his son from studying mathematics, John in turn tried to push Daniel into business [1]. However, when only ten years old, Daniel started to receive lessons in

mathematics from his older brother, Nicholas III. For a while, after a change of heart, he also studied with his father. Eventually, however, he chose medicine as a career instead and graduated in that discipline from Heidelberg in 1721 [5]. A subsequent falling out with his father caused Daniel to be banished from the family home.

Daniel is important for his contribution to at least four fields of interest to statisticians: stochastic processes, tests of significance, likelihood, and utility. As regards the former, his attempts to calculate the advantages of vaccination against smallpox are frequently claimed to be the earliest example of an epidemic model, although as Dietz and Heesterbeek have pointed out in their recent detailed examination [4], the model in question is static not dynamic. However, the example is equally interesting as a contribution to the literature on competing risk.

In an essay of 1734, one of several of Daniel's that won the prize of the Parisian Academy of Sciences, he calculates, amongst other matters, the probability that the coplanarity of the planetary orbits could have arisen by chance. Since the orbits are not perfectly coplanar, this involves his calculating the probability, under a null of perfect random distribution, of a result as extreme or more extreme than that observed. This example, rather than Arbuthnot's, is thus perhaps more properly regarded as a forerunner of the modern significance test [10].

More controversial is whether Daniel can be regarded as having provided the first example of the use of the concept of maximizing likelihood to obtain an estimate (*see Maximum Likelihood Estimation*). A careful discussion of Bernoulli's work of 1769 and 1778 on this subject and his friend and fellow Basler Euler's commentary of 1778 has been provided by Stigler [12].

Finally, Daniel Bernoulli's work on the famous St. Petersburg Paradox should be noted. This problem was communicated to Daniel by his cousin Nicholas II and might equally well have been discussed in the section Nicholas II. The problem was originally proposed by Nicholas to Montmort and concerns a game of chance in which B rolls a die successively and gets a reward from A, that is dependent on the number of throws x to obtain the first six. In the first variant, the reward is x crowns. This has

expectation six crowns. This is then regarded as a fair price to play the game. In the second variant, however, the reward is 2^{x-1} and this does not have a finite expectation, thus implying that one ought to be prepared to pay any sum at all to play the game [7]. Daniel's solution, published in the journal of the St. Petersburg Academy (hence the 'St. Petersburg Paradox') was to replace money value with utility. If this rises less rapidly than the monetary reward, a finite expectation may ensue. Daniel's resolution of his cousin's paradox is not entirely satisfactory and the problem continues to attract attention. For example, a recent paper by Pawitan includes a discussion [8].

Binomial Confidence Interval

Let $(x_1, x_2, \dots, x_n)$ be a random sample of size n from a population consisting of a proportion p of “successes” and a proportion $(1 - p)$ of “failures.” We observe s successes in the sample and now require a $(1 - \alpha)$ 100% **confidence interval** (CI) for p .

Often, the confidence interval is constructed as a complement to a set of null-hypothesis tests. If a hypothesized value, θ_0 , for a parameter θ lies within the bounds to a $(1 - \alpha)$ 100% CI for that parameter, then we ought not reject the hypothesis that $\theta = \theta_0$ at the α significance level. Equivalently, the $(1 - \alpha)$ 100% CI for θ can be defined as the set of values for θ_0 that cannot be rejected at the α significance level. This logic guided the definition in 1934 of what has come to be known as the Clopper–Pearson [2] or exact CI for the binomial parameter p .

Having observed s successes in a random sample of n observations, we would reject the hypothesis $p = p_0$ at the α significance level if, under this hypothesis, either the probability of observing s or fewer successes or the probability of observing s or more successes does not exceed $\alpha/2$. That is, we take the test to be a nondirectional one with the probability of a Type I error divided equally between the two directions.

The probability of s or fewer successes in a random sample of size n , where the probability of a success at each draw is p , is given by a sum of binomial terms,

$$\sum_{y=0, \dots, s} \left\{ \frac{n!}{[y! \times (n - y)!]} p^y (1 - p)^{n-y} \right\}, \quad (1)$$

and the probability of s or more successes by a second sum,

$$\sum_{y=s, \dots, n} \left\{ \frac{n!}{[y! \times (n - y)!]} p^y (1 - p)^{n-y} \right\}. \quad (2)$$

The upper and lower bounds to the $(1 - \alpha)$ 100% CI are given by the values of p that equate each of these sums to $\alpha/2$:

$$\frac{\alpha}{2} = \sum_{y=0, \dots, s} \left\{ \frac{n!}{[y! \times (n - y)!]} p U^y (1 - p_U)^{n-y} \right\}. \quad (3)$$

and

$$\frac{\alpha}{2} = \sum_{y=s, \dots, n} \left\{ \frac{n!}{[y! \times (n - y)!]} p_L^y (1 - p_L)^{n-y} \right\}. \quad (4)$$

Although the required proportions, p_L and p_U , cannot be found directly from the formulae, these bounds have been tabulated for a range of values of n , s , and α , for example, in [3].

Many statistical packages can routinely produce such exact binomial CIs. As an example, the **binom.test** function in the **R** statistical computing language (www.R-project.org) reports, for $n = 12$ and $s = 5$, lower and upper bounds to a 95% CI of 0.1516 and 0.7233.

Owing to the discreteness of the binomial random variable, however, these exact binomial CIs may not have the desired coverage probabilities. That is, CIs defined in this manner may not cover the true value of the success parameter $(1 - \alpha)$ 100% of the time. The use of a carefully selected normal approximation has been shown to improve coverage [1]. One of the approximations recommended, for example, by [1] and [4], is easily implemented. The lower and upper limits to a $(1 - \alpha)$ 100% binomial CI are approximated by

$$p_{\text{adj}} \pm z_{\alpha/2} \left[\frac{p_{\text{adj}}(1 - p_{\text{adj}})}{n} \right],$$

where $p_{\text{adj}} = (s + 2)/(n + 4)$ and $z_{\alpha/2}$ is the $(\alpha/2)$ quantile of the standard normal distribution. For example, 2.5% of the standard normal distribution falls below -1.96 .

For our example, $s = 5$ and $n = 12$, the approximated lower and upper bounds to a 95% CI for p are 0.1568 and 0.7182. In this instance, they differ only slightly from the exact binomial CI limits.

Binomial Distribution: Estimating and Testing Parameters

Binomial Test

The binomial distribution (*see Catalogue of Probability Density Functions*) is generally used to model the proportion of binary trials (that can turn out one of two ways) in which a ‘success’ results. For example, each member of a given set of N adolescents may be classified as a smoker or as a nonsmoker. If some assumptions are met, then the number of smokers in this set follows the binomial distribution. The assumptions required are as follows:

1. Each adolescent may be classified as only a smoker or a nonsmoker, and the definition of what constitutes a smoker is common to all adolescents.
2. Each adolescent has the same probability, p , of being a smoker.
3. There is independence, in that the decision of one adolescent to smoke has no bearing on the decision of any other adolescent to smoke.

Each of these assumptions may be challenged. Regarding the first, it is certainly more informative to classify potential smokers on the basis of the amount they smoke, including possibly not at all. In fact, dichotomizing this inherently continuous smoking variable can result in a loss of **power** if the smoking variable is the dependent variable [3, 7, 8], or in a reversal of the direction of the effect if it is a predictor [6]. The second assumption would be violated if parents who smoke are more likely to have children who smoke. The third assumption, independence, seems questionable if smoking is the result of peer pressure to do so. Nevertheless, we proceed with the binomial distribution, because, sometimes, binomial data are the best (or only) data available. The observed number of smokers, r , in a sample of n adolescents, is represented as an observation on a random variable X , which, if all the assumptions are true, follows the binomial distribution with parameters n (the number of ‘trials’) and p (the ‘success’

probability):

$$P(X = r) = \frac{n!}{[r!(n-r)!]} p^r (1-p)^{n-r},$$
$$r = 0, 1, \dots, n. \quad (1)$$

While there are cases in which one would want to study and estimate the size of a population (what we call N), we consider cases in which N is known prior to conducting the experiment. In many of these cases, it is of interest to learn about the binomial proportion or success probability, p . One may calculate p quite simply as the ratio of the observed frequency of successes in the population to the size N of the population. If, however, it is not feasible to study an entire population and find the numerator of the aforementioned ratio, then p may not be calculated, and it must instead be estimated. The estimation of p is also fairly straightforward, as a sample of size n may be taken, hopefully a representative sample, and then this sample may serve as the population, so that p is calculated on the sample and then used as an estimate for the population.

Clearly, this estimate will not be a very good one if the sampling schemes systematically overrepresents some segments of the population relative to others [5]. For example, if one wanted to study the proportion of a given population that was on a diet, then the local gym would probably not be the best place to conduct the survey, as there could be a bias toward either inflated estimation (more health-conscious people diet and exercise) or deflated estimation (fewer people who exercise are overweight). This concern is beyond the scope of the present article, as it presupposes that there are recognizable subsets (in the example, members of a gym would be a recognizable subset) of the population with a success probability that differed from that of the population at large. If this were the case, then the heterogeneity would invalidate the second binomial assumption.

While estimation is a useful procedure in some contexts, it is also often useful to conduct a formal one-sample hypothesis test that specifies, as its null hypothesis, that the population success proportion p is equal to some prespecified number p_0 . For example, if a claim is made that a certain treatment can make it more or less likely that a child will be born a boy, then one might take the ‘null’ success probability to be 0.5 (to reflect the null state in which girls and boys are equally likely) and ask if 0.5 is still

2 Binomial Distribution

the success probability once this treatment is used. If so, then the treatment has not had its intended effect, but if not, then perhaps it has (depending on the direction of the shift). This analysis could be set up as a two-sided test:

$$\begin{aligned} H_0: p &= 0.5 \text{ versus} \\ H_A: p &\neq 0.5 \end{aligned} \quad (2)$$

or as a one-sided test in either of two directions:

$$\begin{aligned} H_0: p &= 0.5 \text{ versus} \\ H_A: p &> 0.5 \end{aligned} \quad (3)$$

or

$$\begin{aligned} H_0: p &= 0.5 \text{ versus} \\ H_A: p &< 0.5 \end{aligned} \quad (4)$$

To test any of these hypotheses, one would use the **binomial test**. The binomial test is based on the binomial distribution with the null value for p (in this case, the null value is $p = 0.5$), and whatever n happens to be appropriate. The binomial test is generally conducted by specifying a given significance level, α , although one could also provide a P value, thereby obviating the need to specify a given significance level. If α is specified and we are conducting a one-sided test, say with $H_A: p > 0.5$, then the rejection region will consist of the most extreme observations in the direction of the hypothesized effect. That is, it will take a large number of successes, r , to reject H_0 and conclude that $p > 0.5$.

There is some integer, k , which is termed the *critical value*. Then H_0 is rejected if, and only if, the number of successes, r , is at least as large as k . What the value of k is depends on α , as well as on n and p . The set of values of the random variable $\{X \geq k\}$ makes up a rejection region. The probability (computed under the null hypothesis) that the binomial random variable takes a value in the rejection region cannot exceed α and should be as close to α as possible. As a result, the critical value k is the smallest integer for which $P_0\{X \geq k\} \leq \alpha$. This condition ensures that the test is exact [1, 4].

Because the distribution of the number of successes is discrete, it will generally turn out that for the critical k $P_0\{X \geq k\}$ will be strictly less than α . That is, we will be unable to find a value of k for

which the null probability of a success count in the rejection region will be exactly equal to α . When $P_0\{X \geq k\} < \alpha$, the test is said to be conservative. That is, the probability of a Type I error will be less than an intended or nominal significance level α .

The actual level of significance, α' , is computed as

$$\begin{aligned} P_0\{X \geq k\} &= \sum_{r=k, \dots, n} \left\{ \frac{n!}{[r!(n-r)!]} p_0^r (1-p_0)^{n-r} \right\} \\ &= \alpha' \end{aligned} \quad (5)$$

and should be reported. The value of α' depends only on n , p_0 , and α (these three determine k) and can be computed as soon as these parameters are established.

It is a good idea to also report P values, and the P value can be found with the above formula, except replacing k with the observed number of successes. The discreteness of the binary random variable and consequent conservatism of the hypothesis test can be managed by reporting a P value interval [2].

This discussion was based on testing H_0 against $H_A: p > p_0$, but with an obvious modification it can be used also for testing H_0 against $H_A: p < p_0$. In this case, the rejection region would be on the opposite side of the distribution, as we would reject H_0 for small values of the binomial X . The modification for the two-sided test, $H_A: p \neq p_0$, is not quite as straightforward, as it requires rejecting H_0 for either small or large values of X . Finally, we mention that with increasing frequency one encounters tests designed to establish not superiority but rather **equivalence**. In such a case, H_0 would specify that p is outside a given equivalence interval, and the rejection region would consist of intermediate values of X .

As mentioned, the binomial test is an **exact test** [1, 4], but when $np \geq 5$ and $n(1-p) \geq 5$, it is common to use the normal distribution to approximate the binomial distribution. In this situation, the z -test may be used as an approximation of the binomial test.

Binomial Effect Size Display

The binomial effect size display (BESD) was introduced in 1982 as an intuitively appealing general purpose display of the magnitude of experimental effect (*see Effect Size Measures*) [3]. Although there had been a growing awareness of the importance of estimating sizes of effects along with estimating the more conventional levels of significance, there was still a problem in interpreting various effect size estimators such as the **Pearson correlation r** . For example, experienced behavioral researchers and experienced statisticians were quite surprised when they were shown that the Pearson r of 0.32 associated with a coefficient of determination (r^2) of only 0.10 was the correlational equivalent of increasing a success rate from 34 to 66% by means of an experimental treatment procedure; for example, these values could mean that a death rate under the control condition is 66% but is only 34% under the experimental condition. There appeared to be a widespread tendency to underestimate the importance of the effects of behavioral (and biomedical) interventions simply because they are often associated with what are thought to be low values of r^2 [2, 3]. The interpretation of the BESD is quite transparent, and it is useful because it is (a) easily understood by researchers, students, and lay persons; (b) applicable in a wide variety of contexts; and (c) easy to compute.

The question addressed by the BESD is: What is the effect on the success rate (survival rate, cure rate, improvement rate, selection rate, etc.) of instituting a certain treatment procedure? It displays the change in success rate (survival rate, cure rate, improvement rate, selection rate, etc.) attributable to a certain treatment procedure. An example shows the appeal of the procedure.

In their **meta-analysis** of psychotherapy outcome studies, Smith and Glass [5] summarized the results of some 400 studies. An eminent critic stated that the results of their analysis sounded the ‘death knell’ for psychotherapy because of the modest size of the effect. This modest effect size was calculated to be equivalent to an r of 0.32 accounting for ‘only’ 10% of the variance.

Table 1 is the BESD corresponding to an r of 0.32 or an r^2 of 0.10. The table shows clearly that

Table 1 The binomial effect size display: an example ‘Accounting for Only 10% of the Variance’

Condition	Treatment outcome		Σ
	Alive	Dead	
Treatment	66	34	100
Control	34	66	100
Σ	100	100	200

Table 2 Binomial effect size displays corresponding to various values of r^2 and r

r^2	r	Success rate increased		Difference in success rates
		From	To	
0.01	0.10	0.45	0.55	0.10
0.04	0.20	0.40	0.60	0.20
0.09	0.30	0.35	0.65	0.30
0.16	0.40	0.30	0.70	0.40
0.25	0.50	0.25	0.75	0.50
0.36	0.60	0.20	0.80	0.60
0.49	0.70	0.15	0.85	0.70
0.64	0.80	0.10	0.90	0.80
0.81	0.90	0.05	0.95	0.90
1.00	1.00	0.00	1.00	1.00

it would be misleading to label as ‘modest’ an effect size equivalent to increasing the success rate from 34 to 66% (e.g., reducing a death rate from 66 to 34%).

Table 2 systematically shows the increase in success rates associated with various values of r^2 and r . Even so ‘small’ an r as 0.20, accounting for only 4% of the variance, is associated with an increase in success rate from 40 to 60%, such as a reduction in death rate from 60 to 40%. The last column of Table 2 shows that the difference in success rates is identical to r . Consequently, the experimental success rate in the BESD is computed as $0.50 + r/2$, whereas the control group success rate is computed as $0.50 - r/2$. When researchers examine the reports of others and no effect size estimates are given, there are many equations available that permit the computation of effect sizes from the sample sizes and the significance tests that have been reported [1, 4, 6].

Binomial Test

The Binomial Distribution as Theoretical Model For Empirical Distributions

Several statistical tests are based on the assumption that all elements of a sample follow an identical distribution. Designing and analyzing experiments and surveys require us to select a suitable theoretical model (distribution) to represent the empirical distribution. The **binomial distribution** is a probability distribution and a suitable theoretical model for many of the empirical distributions we encounter in social science experiments and surveys. It describes the behavior of a count variable (more specifically, the probability of observing a particular value of the count variable) if the following conditions are met.

1. The number of observations or trials, n , is fixed. The number of trials resulting with the first of the two possible outcomes is x .
2. The observations are independent.
3. Each observation represents one of two outcomes. The probabilities corresponding to the two outcomes are p , for the first of the two possible outcomes and q , for the second of two possible outcomes. They add up to 1.0, so, often only the probability for p is given, and the probability for q is $1 - p$.
4. The probability of the outcomes is the same for each trial.

The process defined by the four conditions is also called *Bernoulli process* or *sequence of Bernoulli trials* (after Jacques Bernoulli, a Swiss mathematician, 1654–1705) (see **Bernoulli Family**), and some statistical text books will refer to the binomial distribution as the *Bernoulli distribution*.

Count variables we observe in social sciences include the number of female students affiliated to a specific department, the number of people volunteering for social work, the number of patients recovering after obtaining a new treatment, the number of subjects solving a puzzle in a problem-solving task. Note that there are many variables, which already represent one of two outcomes: There are either male or female students, people are volunteering or not, puzzles can be solved or not. Other variables may have to be transformed in order to represent only two possible outcomes.

In general, a probability distribution is specified by a probability function that describes the relationship between random events and random variables. With countable finite values for the random variable, the binomial distribution is classified as a discrete probability function. The binomial distribution is a function of n and p .

The resulting empirical distribution when tossing a coin several times is a typical example to illustrate the parameters n and p that specify a binomial distribution: When tossing several times (n = number of coin tosses), we observe the first of the two outcomes, the result head, for a certain number of tosses (x = number of trials with result head). X can randomly take one of the values of k ($k = 0, 1, 2, \dots, n$). Therefore, k is called *random variable*.

To use the binomial function as a theoretical model for describing this empirical function, we additionally need to specify the relationship between the random event of tossing the coin and the random variable. This assumption about the relationship is expressed as a probability (p) for one of the two possible outcomes and can be derived either theoretically or empirically. When tossing a coin, one usually has the idea (theory) of using a fair coin and one would expect the result ‘head’ in about 50% of all tosses. The theoretically derived probability for the value ‘head’ is therefore $p = 0.5$.

We also can see that the required conditions for using the binomial distribution as a theoretic model apply in this example: The number of observations of coin tosses is fixed, each coin toss can be performed independently from the other tosses, there are only two possible outcomes – either head or tail – and, unless we manipulate the coin between two tosses, the probability of the outcome is the same for each trial.

Formally expressed, we say: A variable x with probability function

$$P(x = k) = \binom{n}{k} p^k (1 - p)^{n-k} \quad (1)$$

for $k = 0, 1, 2, \dots, n$; $0 < p < 1$ is called a *binomial variable* whose distribution has parameters n and p .

We can now calculate the probability of observing the outcome ‘head’ x times in $n = 10$ coin tosses by entering the respective values of the binomial distribution ($n = 10$, $p = 0.5$, $x = 0, 1, 2, \dots, n$) in

2 Binomial Test

the probability function (1), as done here as an example for the value $x = 7$.

$$\begin{aligned}
 P(x = 7) &= \binom{10}{7} \times 0.5^7 \times (0.5)^3 \\
 &= \frac{10!}{7! \times (10 - 7)!} \times (0.5)^{10} \\
 &= \frac{10 \times 9 \times 8 \times 7 \times 6 \times 5 \times 4 \times 3 \times 2 \times 1}{(7 \times 6 \times 5 \times 4 \times 3 \times 2 \times 1) \times (3 \times 2 \times 1)} \\
 &\quad \times (0.5)^{10} = 0.117. \quad (2)
 \end{aligned}$$

The probability of observing seven times ‘head’ in 10 trials is 0.117, which is a rather small probability, and might leave us with some doubt whether our coin is really a fair coin or the experimenter did the tosses really independently from each other. Figure 1(a) gives us the probability distribution for the binomial variable x . The text book of Cohen [1, p. 612] gives a simple explanation of what makes the binomial distribution a distribution: ‘The reason you have a distribution at all is that whenever there are n trials, some of them will fall into one category and some will fall into the other, and this division into categories can change for each new set of n trials.’

The resulting probability distribution for the coin toss experiment is symmetric; the value $p = 0.5$ is indicating this already. The distribution in Figure 1(b) illustrates what happens when the value for p increases, for example, when we have to assume that

the coin is not fair, but biased showing ‘head’ in 80% of all tosses.

There are some other details worth knowing about the binomial distribution, which are usually described in length in statistical text books [1, 4]. The binomial mean, or the expected count of success in n trials, is $E(X) = np$. The standard deviation is $\text{Sqrt}(npq)$, where $q = 1 - p$. The standard deviation is a measure of spread and it increases with n and decreases as p approaches 0 or 1. For any given n , the standard deviation is maximized when $p = 0.5$.

With increasing n , the binomial distribution can be approximated by the normal distribution (with or without continuity correction), when p indicates a symmetric rather than an asymmetric distribution. There is no exact rule when the sample is large enough to justify the normal approximation of the binomial distribution, however, a rule of thumb published in most statistical text books is that when p is not near 0.5, npq should be at least 9. However, according to a study by Osterkorn [3], this approximation is already possible when np is at least 10.

The Binomial Test

However, the possibility of deriving the probability of observing a special value x of a count variable by means of the binomial distribution might be interesting from a descriptive point of view. The

Figure 1 Probability function for the binomial distribution with $n = 10$ and $p = 0.5$ (a) coin toss example and $n = 10$ and $p = 0.8$ (b)

Table 1 Data of the coin toss experiment

Outcome		Observed ratio	Expected ratio
Outcome 1: 'head'	$k = 7$	$p1 = 0.7$	$p = 0.5$
Outcome 2: 'tail'	$n - k = 3$	$p2 = 0.3$	$1 - p = 0.5$
	$n = 10$		

value of the binomial distribution for planning and analyzing social science experiments comes with the possibility of using statistical tests based on the binomial distribution. If the binomial distribution is a suitable theoretical model for describing the expected empirical distribution, the binomial test can be applied. The binomial test is also known by the name *sign test*.

In the coin toss experiment with 10 trials introduced above, we observed 7 'heads' and 3 'tails'. On the basis of our assumption of a fair coin, we expected 5 'heads' and 5 'tails' (see Table 1).

One might argue that the observed deviation is small and due to chance. Using the binomial test, we can examine our argument by using the principle of testing statistical hypotheses: Predefining a probability for rejecting the null hypothesis (α) and comparing the observed probabilities for a statistical hypothesis to decide about rejecting the statistical hypothesis.

The Statistical Hypothesis of the Binomial Test

The binomial test gives us a probability for the assumption that the observed frequencies are equal to the expected frequencies. This probability can then be compared to the predefined α -level to decide about keeping or rejecting this assumption.

In our example, we propose the hypothesis that the observed probability for the outcome head (0.7) is no different than the theoretic expected probability for the outcome head (0.5).

How to Perform the Test

To perform a binomial test, we have to find the probability (P) that corresponds to a tail containing x or more extreme values. Formula 3 shows how this is done in general for the one-sided test, giving the probability that the observed ratio for outcome 1 is

smaller than or equal to the expected ratio:

$$P = \sum_{i=0}^k \binom{n}{i} p^i (1-p)^{n-i}. \quad (3)$$

As in our example, the observed ratio for outcome 1 'head' is already larger than the expected ratio, testing this side of the hypothesis makes no sense. Inserting $k = 7$ and $p = 0.5$ from Table 1 in (3) will not yield a useful result. We need to transform the problem to apply the test: $k' = N - k = 3$, $p' = 1 - p = 0.5$ and we are now testing the hypothesis that the observed probability for the outcome 'not head' (0.3) is the same as the theoretical expected probability for the outcome 'not head' (0.5). Formally expressed, we write: $H_0: p = 0.5$; $H_A: p < 0.5$; $\alpha = 0.05$. Using only a calculator, we can perform an exact binomial test for this problem by summarizing the following probabilities:

$$\begin{aligned} P(x = 0) &= \binom{10}{0} \times 0.5^7 \times (0.5)^3 = 0.001 \\ P(x = 1) &= \binom{10}{1} \times 0.5^7 \times (0.5)^3 = 0.0098 \\ P(x = 2) &= \binom{10}{2} \times 0.5^7 \times (0.5)^3 = 0.0439 \\ P(x = 3) &= \binom{10}{3} \times 0.5^7 \times (0.5)^3 = 0.1172 \\ P &= 0.1719. \end{aligned} \quad (4)$$

The probability to observe 3 or fewer times the outcome 'not head' in 10 trials is $P = 0.1719$. This value is larger than the significance level of 0.05, and therefore we keep the hypothesis of equal observed and expected ratio. According to this result, we have a fair coin.

Performing the exact binomial test for a larger sample is rather difficult and time consuming (see **Exact Methods for Categorical Data**). Statistic text books therefore recommend the asymptotic binomial test, on the basis of the fact that the binomial distribution can be approximated by the normal distribution when the sample is large, thus allowing a more convenient z-test [1, 4].

4 Binomial Test

Table 2 Data of the ‘representative sample’ example. Statistical hypothesis: The observed ratio of males and females is equal to the expected ratio. $H_0: p = 0.5$; $H_A: p \neq 0.5$; $\alpha = 0.05$

Sex	Observed ratio	Expected ratio
Group 1: ‘male’	$k = 16$	$p1 = 0.17$
Group 2: ‘female’	$n - k = 76$	$p2 = 0.83$
	$n = 92$	$1 - p = 0.5$

Note: Asymptotic significance, two-tailed: $P = 0.000$
 $P = 0.000 < \alpha = 0.05$, reject H_0 .

Some Social Science Examples for Using the Binomial Test Using SPSS

Example 1: A natural grouping variable consisting of two mutually exclusive groups 92 subjects volunteered in a research project. 16 of them are males, 76 are females. The question arises whether this distribution of males and females is representative or whether the proportion of males in this sample is too small (Table 2).

Using SPSS, the syntax below, we obtain a P value for an asymptotic significance (two-tailed), which is based on the z-approximation of the binomial distribution: $P = 0.000$.

NPART TEST

/BINOMIAL (0.50) = sex.

The decision to calculate the two-tailed significance is done automatically by the software, whenever the expected ratio is 0.5. Still, we can interpret a one-sided hypothesis. As the distribution is symmetric, when $p = 0.5$, all we have to do is to divide the obtained P value by two. In our example, the P value is very small, indicating that the statistical hypothesis of equal proportions is extremely unlikely ($P = 0.000 < \alpha = 0.05$, reject H_0). We therefore reject the H_0 and assume that the current sample is not representative for males and females. Males are underrepresented.

Example 2: Establishing two groups by definition

In Example 1, we used a natural grouping variable consisting of two mutually exclusive groups. In Example 2, we establish the two groups on the basis of empirical information.

For the assessment of aspiration level, 92 subjects volunteered to work for 50 sec on a speeded

Table 3 Data of the ‘aspiration level’ example. Statistical hypothesis: The observed ratio of optimistic performance prediction is equal to the expected level of performance prediction. $H_0: p = 0.5$; $H_A: p \neq 0.5$; $\alpha = 0.05$

Group	Observed ratio	Expected ratio
Group 1: ‘optimistic’	$k = 65$	$p1 = 0.71$
Group 2: ‘pessimistic’	$n - k = 27$	$p2 = 0.29$
	$n = 92$	$1 - p = 0.5$

Note: Asymptotic significance, two-tailed: $P = 0.000$
 $P = 0.000 < \alpha = 0.05$, reject H_0 .

symbol-coding task (Table 3). Afterward, they were informed about their performance (number of correct), and they provided a performance prediction for the next trial. We now use the binomial test to test whether the ratio of subjects with optimistic performance prediction (predicted increase of performance = group 1) and pessimistic performance prediction (predicted decrease of performance = group 2) is equal.

The significant result indicates that we can reject the null hypothesis of equal ratio between optimistic and pessimistic performance prediction. The majority of the subjects expect their performance to increase in the next trial.

Example 3: Testing a hypothesis with more than one independent binomial test

As we know, our sample of $n = 92$ is not representative regarding males and females (see Example 1). Thus, we might be interested in testing whether the tendency to optimistic performance prediction is the same in both groups. Using the binomial test, we perform two statistical tests to test the same hypothesis (Table 4). To avoid accumulation of statistical error, we use Bonferroni-adjustment (see **Multiple Comparison Procedures**) $\alpha' = \alpha/m$ (with m = number of statistical tests performed to test one statistical hypothesis) and perform the binomial tests by using the protected α level (see [2] for more information on Bonferroni-adjustment).

The significant result for the females indicates that we can reject the overall null hypothesis of equal ratio between optimistic and pessimistic performance prediction for males and for females. Although not further discussed here, on the basis of the current

Table 4 Data of the ‘aspiration level’ example – split by gender. Statistical hypothesis: The observed ratio of optimistic performance prediction is equal to the expected level of performance prediction. Test 1: male; Test 2: female $H_0: p = 0.5$ for males and for females; $H_A: p \neq 0.5$ for males and/or females; $\alpha = 0.05$

		Observed ratio	Expected ratio
Male			
Group 1: ‘optimistic’	$k = 12$	$p1 = 0.75$	$p = 0.5$
Group 2: ‘pessimistic’	$n - k = 4$	$p2 = 0.25$	$1 - p = 0.5$
	$n = 16$		
Exact significance, two-tailed: $P = 0.077$			

		Observed ratio	Expected ratio
Female			
Group 1: ‘optimistic’	$k = 53$	$p1 = 0.70$	$p = 0.5$
Group 2: ‘pessimistic’	$n - k = 23$	$p2 = 0.30$	$1 - p = 0.5$
	$n = 76$		
Asymptotic significance, two-tailed: $P = 0.001$			

Note: Adjusted $\alpha: \alpha' = \alpha/m$; $\alpha = 0.05$, $m = 2$, $\alpha' = 0.025$; $P(\text{male}) = 0.077 > \alpha' = 0.025$, retain H_0 for males; $P(\text{female}) = 0.001 < \alpha' = 0.025$, reject H_0 for females.

data, we may assume equal proportion of optimistic and pessimistic performance predictions for males, but not for females. The current female sample tends to make more optimistic performance predictions than the male sample.

Example 4: Obtaining p from another sample

The previous examples obtained p for the binomial test from theoretical assumptions (e.g., equal distribution of male and females; equal distribution of optimistic and pessimistic performance). But there are other sources of obtaining p that might be more interesting in social sciences. One source for p might be a result found with an independent sample or published in literature.

Continuing our aspiration level studies, we are interested in situational influences and are now collecting data in real-life achievement situations

Table 5 Data of the ‘comparing volunteers and applicants’ example. Statistical hypothesis: Applicants’ (observed) ratio of optimistic performance prediction is equal to the expected level of performance prediction. $H_0: p = 0.7$; $H_A: p > 0.7$; $\alpha = 0.05$

Group		Observed ratio	Expected ratio
Group 1: ‘optimistic’	$k = 21$	$p1 = 0.87$	$p = 0.7$
Group 2: ‘pessimistic’	$n - k = 3$	$p2 = 0.13$	$1 - p = 0.3$
	$n = 24$		

Note: Exact significance, one-tailed: $P = 0.042$
 $P = 0.042 < \alpha = 0.05$, reject H_0 .

rather than in the research-lab situation. 24 females applying for a training as air traffic control personnel did the coding task as part of their application procedure. 87% of them gave an optimistic prediction.

Now we remember the result of Example 3. In the research lab, 70% of the females had made an optimistic performance prediction, and we ask whether these ratios of optimistic performance prediction are the same (Table 5).

On the basis of the binomial test result, we reject the null hypothesis of equal ratios of optimistic performance prediction between the volunteers and the applicants. Female applicants are more likely to give optimistic than pessimistic performance predictions.

Biplot

Biplots are of two basic kinds (a) those concerned with a multivariate data matrix of a sample of n cases with observations on p variables (see **Multivariate Analysis: Overview**) and (b) those concerned with a single variable classified into a two-way table with r rows and c columns. In both cases, the aim is to give a visual representation in a few dimensions that approximates the values of the data matrix or table, as the case may be. The *bi* in biplots denotes the two modes: in case (a) samples and variables and in case (b) rows and columns. Thus, biplots are not necessarily two dimensional, though they often are. Biplots are useful for detecting patterns possibly suggesting more formal analyses and for displaying results found by more formal methods of analysis. In the following, cases (a) and (b) are treated briefly; for further details see Gower and Hand [3].

The simplest and commonest form of multivariate biplot uses **principal component analysis** (PCA) to represent the cases by n points and the variables by p vectors with origin 0. Then, the length of the projection of the point representing the i th case onto the j th vector predicts the observed (i, j) th value [2]. Gower and Hand [3] replace the vectors by bipolar axes equipped with numerical scales: then the values associated with the projections are immediate. This biplot is essentially a generalized **scatterplot** with more axes, necessarily nonorthogonal, than dimensions. The biplot axes are approximations of the full Cartesian representations with p orthogonal axes, where intercase distances are given by Pythagoras' distance formula (Figure 1). Similar approaches may be used with other distances and other methods of **multidimensional scaling**, when the scale markers on the axes may become nonlinear (see e.g., a logarithmic scale) and the axes themselves may be nonlinear.

Categorical variables, not forming a continuous scale, need special consideration. Each is represented by a set of *category-level-points* (CLPs) one for each category-level; CLPs for ordered categories are collinear. In contrast to a numerical scale, CLPs are labeled by the names of their category levels. In exact representations, the point representing a case is nearer the labels that give the values of its variables than to any other labels. In approximations, we need to predict what are the nearest

Figure 1 A principal component biplot with 21 cases (aircraft), labeled alphabetically, and four quantitative variables (RGF, SPR, PLF, SLF) referring to performance represented as four scaled biplot axes. This is a version of Figure 2.8 of Gower and Hand [3] modified to emphasize the close relationship between biplot axes and conventional coordinate axes. Predicted values are read off by projecting onto the axes, in the usual way

CLPs and this is done by creating a set of convex regions known as *prediction regions*; a point representing a case is then predicted as having the labeled categories of the prediction regions within which it lies. This setup applies to multiple correspondence analysis (MCA) with its dependence on chi-squared distance but it also applies to any form of distance defined for categorical variables. Figure 2 shows a biplot for ordered categorical variables. Numerical and categorical variables may be included in the same biplot. As well as prediction, sometimes one wishes to add a new sample to a multidimensional scaling display. This interpolation requires a different set of biplot axes than those required for prediction.

A two-way table can always be treated as a data matrix and the previously discussed forms of biplot used. However, the cases and variables of a multivariate data matrix are logically different noninterchangeable entities, whereas the rows and columns of a two-way table may be interchanged. Rows and columns are given parity when each is represented by sets of points without scaled axes. For categorical variables, the table is a **contingency table** and we have **correspondence analysis** biplots. For a

2 Biplot

Figure 2 This is a nonlinear principal components biplot, showing 14 ordered categorical variables, A–E giving attitudes to regional identity and O–W giving attitudes to national identity. Each variable has four levels, ‘very’, ‘somewhat’, ‘a little’ and ‘none’ shown as black, dark gray, light gray and unshaded markers, triangular for regional identity and circular for national identity. Just four, of nearly 1000, cases are illustrated. Predictions associated with a case are given by the labels of the nearest markers on each axis. The data refer to Great Britain in the International Social Survey Program for 1995 and are fully discussed by Blasius and Gower [1]

tabulated quantitative variable, the biplot represents the multiplicative interaction term of a biadditive model. In both cases, interpretation is by evaluating the inner product $OR_i \times OC_j \times \cos(R_i OC_j)$, where R_i and C_j are the points representing the i th row and j th column, respectively.

Block Random Assignment

The validity of the comparison between any two treatment groups is predicated on the comparability of these two treatment groups in all relevant respects other than the treatments under study (*see Clinical Trials and Intervention Studies*). Without this condition, any observed differences in the outcomes across the treatment groups can be attributed to either the treatments or the underlying differences having nothing to do with the treatments. To definitively attribute observed differences to the treatments themselves (the intended conclusion), all competing potential attributions must be falsified. For example, if alcohol consumption is observed to be positively associated with certain types of cancer, but alcohol consumption is also observed to be positively associated with tobacco consumption, which in turn is positively associated with these same types of cancer, then tobacco use is a confounder (*see Confounding Variable*).

Without additional information, it is impossible to distinguish between alcohol being truly carcinogenic and alcohol being nothing more than a benign correlate of tobacco use. These are the two extremes explanations, and in the middle one would consider explanations involving attributable fractions. Clearly, confounding can lead to complicated analyses and interpretations, and hence steps are often taken to control, minimize, or eliminate confounding. One such step is **randomization**, which can be conducted for any of several reasons, but one of the best is the creation of comparable comparison groups. Often, discussions of confounding end as soon as randomization is mentioned. That is, there appears to be a widely held belief that randomization by itself can eliminate all confounding, and ensure that any baseline differences between comparison groups formed by randomization are necessarily random and, by implication, unimportant. These views are not only wrong, but they are also dangerous.

In reality, there are many types of randomization, and each is susceptible to various types of bias. Prominent among these various biases are chronological bias resulting from time trends and selection bias resulting from prediction of upcoming allocations. To understand these biases, consider one of

the simplest types of randomization, specifically the random allocation rule [7] by which randomization is unrestricted other than having to adhere to specified allocation proportions. For example, if there are 200 subjects to be randomized, 100 to each group, then there are $200!/(100!)^2$ possible ways to split the 200 subjects evenly between the two treatment groups. The random allocation rule assigns equal probability, $(100!)^2/200!$, to each of these possibilities. This randomization procedure allows for long runs of consecutive subjects being allocated to the same treatment condition, so at some point during the study there may be grossly unbalanced numbers of subjects allocated to the two treatment groups.

If, in addition to a gross imbalance, there is also a time trend, then this can lead to imbalance with regard to not only numbers allocated at some point in time but also a covariate, and this imbalance may well remain at the end of the study. For example, at some point during the study, the composition of the subjects entering the study may change because of some external factor, such as new legislation or the approval of a new drug. This may make ‘early’ patients older or younger, or more or less likely to be male or female than ‘late’ patients, in which case this imbalance over time is transferred to imbalance across treatment groups. To prevent chronological bias from occurring, randomization is often restricted, so that at various points in time the number of subjects randomized to each treatment group is the same. This is referred to as blocking, or using randomized blocks, or permuted blocks. Each block is a set of subjects enrolled between consecutive forced returns to perfect balance. Note that the random allocation rule is a randomized block design with one large block, so it is more resistant to chronological bias than is the unrestricted randomization that results from assigning each subject on the basis of a fair coin toss, as the latter would not even ensure comparable group sizes at the end.

When randomized blocks are used, generally randomization is stratified by the block, meaning that the randomization in any one block is independent from the randomization in any other block. This is not always the case, however, as a study of etanercept for children with juvenile rheumatoid arthritis [5] used blocks within two strata, and corresponding blocks in the two strata were mirror images of each other [1].

In the usual case, not only are the blocks independent of each other, but also randomization within

2 Block Random Assignment

any block occurs by the random allocation rule. The block size may be fixed or random. If the block size is fixed at 4, for example, then there are six admissible sequences per block, specifically AABB, ABAB, ABBA, BAAB, BABA, and BBAA, so each would be selected (independently) with probability 1/6 for each block. There are two admissible sequences per block of size 2 (AB and BA), and 20 admissible sequences within each block of size 6. Of course, these numbers would change if the allocation proportions were not 1 : 1 to the two groups, or if there were more than two groups. Certainly, randomized blocks can handle these situations. Following (Table 1) is an example of blocked randomization with 16 subjects and a treatment assignment ratio of 1 : 1. Three randomization schedules are presented, corresponding to fixed block sizes of 2, 4, and 6. One could vary the block sizes by sampling from each of the columns in an overall randomization scheme. For example, the first six subjects could constitute one block of size 6, the next two could be a block of size 2, and the last eight could be two blocks of size 4 each. Note that simply varying the block sizes does not constitute random block sizes. As the name would suggest, random block sizes means that the block sizes not only vary but are also selected by a random mechanism [2].

The patterns within each block are clear. For example, when the block size is 2, the second

assignment depends entirely on the first assignment within each block; when the block size is 4, the fourth assignment is always predetermined, and the third may be as well. The first two are not predetermined, but the second will tend to differ from the first (they will agree in only two of the six possible sequences).

Smaller block sizes are ideal for controlling chronological bias, because they never allow the treatment group sizes to differ appreciably. In particular, the largest imbalance that can occur in any stratum when randomized blocks are used sequentially within this stratum (that is, within the stratum one block starts when the previous one ends) is half the largest block size, or half the common block size if there is a common block size. If chronological bias were the only consideration, then any randomized block study of two treatments with 1 : 1 allocation would be expected to use a common block size of 2, so that at no point in time could the treatment group sizes ever differ by more than one. Of course, chronological bias is not the only consideration, and blocks of size two are far from ideal. As mentioned, as the block size increases, the ability to predict upcoming treatment assignments on the basis of knowledge of the previous ones decreases.

This is important, because prediction leads to a type of selection bias that can interfere with **internal**

Table 1 Examples of Block Random Assignment

Subject	Block size = 2		Block size = 4		Block size = 6	
	Block	Treatment	Block	Treatment	Block	Treatment
1	1	A	1	A	1	A
2		B		A		A
3	2	A		B		B
4		B		B		A
5	3	B	2	A		B
6		A		B		B
7	4	B		B	2	B
8		A		A		B
9	5	B	3	A		A
10		A		B		B
11	6	A		A		A

13	7	A	4	B		B
14		B		B		B
15	8	A		A		B
16		B		A		A

validity, even in randomized trials. Note that a parallel is often drawn between randomized trials (that use random allocation) and random samples, as ideally each treatment group in a randomized trial constitutes a random sample from the entire sample. This analogy requires the sample to be formed first, and then randomized, to be valid, and so it breaks down in the more common situation in which the recruitment is sequential over time. The problem is that if a future allocation can be predicted and the subject to be so assigned has yet to be selected, then the foreknowledge of the upcoming allocation can influence the decision of which subject to select. Better potential responders can be selected when one treatment is to be assigned next and worse potential responders can be selected when another treatment is to be assigned next [3]. This selection bias can render analyses misleading and estimates unreliable.

The connection between blocked designs and selection bias stems from the patterns inherent in the blocks and allowing for prediction of future allocations from past ones. Clearly, the larger the block size, the less prediction is possible, and so if selection bias were the only concern, then the ideal design would be the random allocation rule (that maximizes the block size and minimizes the number of blocks), or preferably even unrestricted randomization. But there is now a trade-off to consider between chronological bias, which is controlled with small blocks, and selection bias, which is controlled with large blocks. Often this trade-off is addressed by varying the block sizes. While this is not a bad idea, the basis for doing so is often the mistaken belief that varying the block sizes eliminates all prediction of future allocations, and, hence, eliminates all selection bias. Yet varying the block sizes can, in some cases, actually lead to more prediction of future allocations than fixed block sizes would [4, 6].

A more recent method to address the trade-off between chronological bias and selection bias is the maximal procedure [4], which is an alternative to randomized blocks. The idea is to allow for any allocation sequence that never allows the groups sizes to differ beyond an acceptable limit. Beyond this, no additional restrictions, in the way of forced returns to perfect balance, are imposed. In many ways, the maximal procedure compared favorably to randomized blocks of fixed or varied size [4].

Boosting

Boosting was introduced by Freund and Schapire in 1996 [2], who developed the *Adaboost* algorithm. Adaboost is an ensemble classifier, which works by voting the predictions of many individual classifiers (*see Discriminant Analysis*). More information about voting ensembles is given in the related article on **bagging**. Another popular boosting algorithm is the LogitBoost algorithm of Friedman et al. 2000 [4]. The main benefit of boosting is that it often improves prediction accuracy, however, the resulting classifier is not interpretable.

The idea behind boosting is to form an ensemble by fitting simple classifiers (so-called base learners) to weighted versions of the data. Initially, all observations have the same weight. As the ensemble grows, we adjust the weights on the basis of our

knowledge of the problem. The weights of frequently misclassified observations are increased, while those of seldom-misclassified observations are decreased. Heuristically, we force the classifiers to tailor themselves to the hard-to-classify cases, and hope that the easy-to-classify cases will take care of themselves.

The base learners vary according to the implementation, and may be as simple as the so-called stumps classifier, which consists of a decision tree with only one split; cases with low values of the split variable are classified as one class and those with high values are classified as the other class. The base learner must allow us to weight the observations. Alternatively, we can randomly sample cases with replacement, with probabilities proportional to the weights, which makes boosting appear similar to bagging. The critical difference is that in bagging, the members of the ensemble are independent; in boosting, they are not.

Figure 1 (a) Data and underlying function; (b) 10 boosted stumps; (c) 100 boosted stumps; (d) 400 boosted stumps

Once we have the ensemble, we combine them by weighted voting. These weights are chosen so that highly accurate classifiers get more weight than do less accurate ones. Again, the particular choice of weights depends on the implementation.

To illustrate, we use the R [8] function Logit-Boost [1] to fit a classifier to the data in Figure 1. The classification boundary and the data are given in Figure 1(a). In Figure 1(b), (c), and (d), the shading intensity indicates the weighted vote for class 1. As more stumps are included, the boosted classifier obtains a smoother, more accurate estimate of the classification boundary; however, it is still not as accurate as bagged trees (see Figure 1d in the article on bagging).

Recent theoretical work, for example [6], has shown that Adaboost is not consistent. That is, there are examples for which Adaboost does not converge to the optimal classification rule. In practice, this means that Adaboost will overfit the data in noisy situations, so it should not be used without some form of **cross validation** to prevent overfitting. For example, we might run the algorithm until the prediction error on a cross validation test set starts to increase.

An application of boosting to dementia data is described in the article on bagging.

Statistical references on boosting include [3], [4] and [5] and a machine learning summary is given in [7]. Related methods include bagging and **random forests**.

Bootstrap Inference

The data analyst buys insight with assumptions – for example that data are independent, or follow a specified distributional form, or that an estimator has a given distribution, typically obtained by a mathematical argument under which the sample size tends to infinity (see **Maximum Likelihood Estimation**). Sometimes these assumptions may be justified by background knowledge or can be checked empirically, but often their relevance to the situation at hand is questionable, and, if they fail, it can be unclear how to proceed. Bootstrap methods are a class of procedures that may enable the data analyst to produce useful results nonetheless.

Consider, for instance, Table 1, which shows how an integer measure `hand` of the degree of left-handedness of $n = 37$ individuals varies with a genetic measure `dnan`. Figure 1 shows a strong positive relation between them, which is tempting to summarize using the sample product–moment correlation coefficient (see **Pearson Product Moment Correlation**), whose value is $\hat{\theta} = 0.509$. If the sample is representative of a population, we may wish to give a **confidence interval** for the population correlation. Exact intervals are hard to calculate, but a standard approximation yields a 95% confidence interval of (0.221, 0.715). This, however, presupposes that the population distribution is bivariate normal (see **Catalogue of Probability Density Functions**), an assumption contradicted by Figure 1. What then is the status of the interval? Can we do better?

Data Resampling

A key aspect of non-Bayesian statistical inference is the use of the sampling variability of an estimator, $\hat{\theta}$, to build inferences for the quantity of interest, θ . This entails using a model, for example, that the observations $y_1, \dots, y_n$ are drawn independently from an underlying population distribution F . In Table 1, each observation y consists of a pair (`dnan`, `hand`), and thus F has support in a subset of the plane. If F were known, the sampling variability of θ could be found either by a theoretical calculation, if this were possible, or empirically, by simulation from F . This latter method entails generating a sample

$y_1^*, \dots, y_n^*$ from F , computing the corresponding value $\hat{\theta}^*$ of the estimator, repeating this sampling procedure R times, and using the resulting replicates $\hat{\theta}_1^*, \dots, \hat{\theta}_R^*$ to estimate the distribution of $\hat{\theta}$. These two possibilities are illustrated in (a) of Figure 2, which superimposes the theoretical density of $\hat{\theta}$ under a fitted bivariate-normal distribution upon a histogram of $R = 10\,000$ values of $\hat{\theta}^*$ simulated from the same bivariate normal distribution. As one would expect, the two are close: if R were increased to infinity, then the histogram would converge to the theoretical density. The power of modern computing means that R is limited only by our impatience for results, but taking R huge is of little use here, because the bivariate-normal distribution fits the data badly. An alternative is to estimate the population F directly from the data using the empirical distribution function $\hat{F}$, which puts probability mass n^{-1} on each of the $y_1, \dots, y_n$. This discrete distribution is in fact the nonparametric **maximum-likelihood estimate** of F : in the present case, it puts masses on the points in Figure 1, proportional to the multiplicities, and with unit total mass.

The bootstrap idea is to use resampling from the fitted distribution $\hat{F}$ to mimic sampling from the distribution F underlying the data. To perform this we take samples $y_1^*, \dots, y_n^*$ of size n with replacement from the original observations $y_1, \dots, y_n$. Thus, for the handedness data, a bootstrap sample is created by taking $n = 37$ pairs (`dnan`, `hand`) from those in Table 1 with replacement and equal probability. Repetitions of the original observations will occur in the bootstrap samples, and though not a problem here, this can have repercussions when the statistic depends sensitively on the exact sample values; in some cases, smoothing or other modifications to the resampling scheme may be required. Panel (b) of Figure 2 shows a histogram of values $\hat{\theta}^*$ computed from 10 000 bootstrap samples, together with the probability density of $\hat{\theta}$ under the bivariate-normal distribution fitted above. The sharp difference between them would not disappear even with an infinite simulation, because the data are nonnormal – the histogram better reflects the sampling variability of the correlation coefficient under the unknown true distribution F .

The bootstrap replicates can be used to estimate sampling properties of $\hat{\theta}$ such as its bias and variance,

2 Bootstrap Inference

Table 1 Data from a study of handedness; hand is an integer measure of handedness and dnan a genetic measure. Data due to Dr Gordon Claridge, University of Oxford

	dnan	hand	dnan	hand	dnan	hand	dnan	hand
1	13	1	11	28	1	21	29	2
2	18	1	12	28	2	22	29	1

9	28	1	19	29	1	29	31	1
10	28	2	20	29	2	30	31	1

Figure 1 Scatter plot of handedness data. The numbers show the multiplicities of the observations

which may be estimated by

$$b = \bar{\theta}^* - \hat{\theta}, \quad v = \frac{1}{R-1} \sum_{r=1}^R (\hat{\theta}_r^* - \bar{\theta}^*)^2, \quad (1)$$

where $\bar{\theta}^* = R^{-1} \sum_{r=1}^R \hat{\theta}_r^*$ is the average of the simulated $\hat{\theta}^*$ s. For the handedness data, we obtain $b = -0.046$ and $v = 0.043$ using the 10 000 simulations shown in (b) of Figure 2.

The simulation variability of quantities such as b and v , which vary depending on the random resamples, is reduced by increasing R . As a general rule, $R \geq 100$ is needed for bias and variance estimators to

be reasonably stable. For the more challenging tasks of constructing confidence intervals or significance tests discussed below, $R \geq 1000$ is needed for 95% confidence intervals, and more resamples are needed for higher confidence levels.

The power of the bootstrap should be evident from the description above: although the correlation coefficient is simple, it could be replaced by a statistic $\hat{\theta}$ of a complexity limited only by the data analyst's imagination and the computing power available – see, for example, the article on **finite mixture distributions**. The bootstrap is not a universal panacea, however, and many of the procedures described below apply only when $\hat{\theta}$ is sufficiently smooth as a function of the data values. The resampling scheme may need careful modification for reliable results.

The discussion above has shown how resampling may be used to mimic sampling variability, but not how the resamples can be used to provide inferences on the underlying population quantities. We discuss this below.

Confidence Intervals

Many estimators $\hat{\theta}$ are normally distributed, at least in large samples. If so, then an approximate equitailed $100(1 - 2\alpha)\%$ confidence interval for the estimand θ is $\hat{\theta} - b \pm z_\alpha \sqrt{v}$, where b and v are given at (1) and z_α is the α **quantile** of the standard normal, $N(0, 1)$, distribution. For the handedness data this gives a 95% interval of (0.147, 0.963) for the correlation θ . The quality of the normal approximation and hence the reliability of the confidence interval can be assessed by graphical comparison of $\hat{\theta}_1^*, \dots, \hat{\theta}_R^*$ with a normal

Figure 2 Histograms of simulated correlation coefficients for handedness data. (a): Simulation from fitted bivariate-normal distribution. (b): Simulation from the data by bootstrap resampling. The line in each figure shows the theoretical probability-density function of the correlation coefficient under sampling from the fitted bivariate-normal distribution

Figure 3 Bootstrap values $\hat{\zeta}^*$ of transformed correlation coefficient ζ . (a): histogram, with vertical dashed line showing original value $\hat{\zeta}$. (b): normal probability plot, with dashed line indicating exact normality

density. The strongly skewed histogram in (b) of Figure 2 suggests that this confidence interval will be quite unreliable for the handedness correlation.

Nonnormality can often be remedied by transformation. In the case of the correlation coefficient,

a well-established possibility is to consider $\zeta = \frac{1}{2} \log\{(1 + \theta)/(1 - \theta)\}$, which takes values in the entire real line rather than just in the interval $(-1, 1)$. Figure 3 shows a histogram and normal probability plot of the values of $\hat{\zeta}^* = \frac{1}{2} \log\{(1 + \hat{\theta}^*)/(1 - \hat{\theta}^*)\}$,

for which the normal distribution is a better, though a not perfect, fit. The 95% confidence interval for ζ computed using values of b and v obtained from the $\hat{\zeta}^*$ s is (0.074, 1.110), and transformation of this back to the original scale gives a 95% confidence interval for θ of (0.074, 0.804), shorter than and shifted to the left relative to the interval obtained by treating the $\hat{\theta}^*$ themselves as normally distributed.

Although simple, normal confidence intervals often require a transformation to be determined by the data analyst, and hence, more readily automated approaches have been extensively studied. The most natural way to use the bootstrap replicates $\hat{\theta}_1^*, \dots, \hat{\theta}_R^*$ of $\hat{\theta}$ to obtain a confidence interval for θ is to use their quantiles directly. Let $\hat{\theta}_{(1)}^* \leq \dots \leq \hat{\theta}_{(R)}^*$ be the ordered bootstrap replicates. Then, one simple approach to constructing an equitailed $100(1 - 2\alpha)\%$ confidence interval is to take the α and $(1 - \alpha)$ quantiles of the $\hat{\theta}^*$, that is, $\hat{\theta}_{(R\alpha)}^*$ and $\hat{\theta}_{(R(1-\alpha))}^*$, where, if necessary, the numbers $R\alpha$ and $R(1 - \alpha)$ are rounded to the nearest integers. Thus, for example, if a 95% confidence interval is required, we set $\alpha = 0.025$ and, with $R = 10\,000$, would take its limits to be $\hat{\theta}_{(250)}^*$ and $\hat{\theta}_{(9750)}^*$. In general, the corresponding interval may be expressed as $(\hat{\theta}_{(R\alpha)}^*, \hat{\theta}_{(R(1-\alpha))}^*)$, which is known as the *bootstrap percentile confidence interval*. This has the useful property of being invariant to the scale on which it is calculated, meaning that the same interval is produced using the $\hat{\theta}^*$ s directly as would be obtained by transforming them, computing an interval for the transformed parameter, and then back-transforming this to the θ scale. Its simplicity and transformation-invariance have led to widespread use of the percentile interval, but it has drawbacks. Typically such intervals are too short, so the probability that they contain the parameter is lower than the nominal value: an interval with nominal level 95% may in fact contain the parameter with probability only .9 or lower. Moreover, such intervals tend to be centered incorrectly: even for equitailed intervals, the probabilities that θ falls below the lower end point and above the upper end point are unequal, and neither is equal to α . For the handedness data, this method gives a 95% confidence interval of $(-0.047, 0.758)$. This seems to be shifted too far to the left relative to the transformed normal interval.

These deficiencies have led to intensive efforts to develop more reliable bootstrap confidence intervals. One variant of the percentile interval, known as the

bias-corrected and accelerated (BC_a) or *adjusted percentile interval*, may be written as $(\hat{\theta}_{(R\alpha')}^*, \hat{\theta}_{(R(1-\alpha''))}^*)$, where α' and α'' are estimated from the $\hat{\theta}_1^*, \dots, \hat{\theta}_R^*$ in such a way that the resulting intervals are closer to equitailed with the required coverage probability $1 - 2\alpha$. Formulae for α' and α'' are given in §5.3 of [2], but often they are built into software libraries for bootstrapping. For the handedness data, we find that $\alpha' = 0.0485$ and $\alpha'' = 0.0085$ resulting in the 95% interval (0.053, 0.792). This method seems to have corrected for the shift to the left we saw in the percentile interval.

Other methods for the calculation of confidence intervals rely on an analogy with the Student t statistic used with normally distributed samples. Suppose that a standard error s for $\hat{\theta}$ is available; then s^2 is an estimate of the variance of $\hat{\theta}$. Then, the basis of more general confidence-interval procedures is the use of bootstrap simulation to estimate the distribution of $z = (\hat{\theta} - \theta)/s$. *Studentized bootstrap confidence intervals* are constructed by using bootstrap simulation to generate R bootstrap replicates $z^* = (\hat{\theta}^* - \hat{\theta})/s^*$, where s^* is the standard error computed using the bootstrap sample that gave $\hat{\theta}^*$. The resulting $z_1^*, \dots, z_R^*$ are then ordered, their α and $(1 - \alpha)$ quantiles $z_{(R\alpha)}^*$ and $z_{(R(1-\alpha))}^*$ obtained, and the resulting $(1 - 2\alpha) \times 100\%$ confidence interval has limits $(\hat{\theta} - sz_{(R(1-\alpha))}^*, \hat{\theta} - sz_{(R\alpha)}^*)$. These intervals often behave well in practice but require a standard error s , which must be calculated for the original sample and each bootstrap sample. If a standard error is unavailable, then the Studentized interval may be simplified to the *bootstrap basic confidence interval* $(2\hat{\theta} - \hat{\theta}_{(R(1-\alpha))}^*, 2\hat{\theta} - \hat{\theta}_{(R\alpha)}^*)$. Either of these intervals can also be used with transformation, but unlike the percentile intervals, they are not transformation-invariant. It is generally advisable to use a transformation that maps the parameter range to the whole real line to avoid getting values that lie outside the allowable range. For the handedness data, the 95% Studentized and basic intervals using the same transformation as before are $(-0.277, 0.868)$ and $(0.131, 0.824)$ respectively. The Studentized interval seems too wide in this case and the basic interval too short. Without transformation, the upper end points of both intervals were greater than 1.

Standard error formulae can be found for many everyday statistics, including the correlation coefficient. If a formula is unavailable, the bootstrap itself can sometimes be used to find a standard error, using

two nested levels of bootstrapping. The bootstrap is applied Q times to each first-level bootstrap sample $y_1^*, \dots, y_n^*$, yielding second-level samples and corresponding replicates $\hat{\theta}_1^{**}, \dots, \hat{\theta}_Q^{**}$. Then, $s^* = \sqrt{v^*}$, where v^* is obtained by applying the variance formula at (1) to $\hat{\theta}_1^{**}, \dots, \hat{\theta}_Q^{**}$. The standard error of the original $\hat{\theta}$ is computed as $s = \sqrt{v}$, with v computed by applying (1) to the first-level replicates $\hat{\theta}_1^*, \dots, \hat{\theta}_R^*$. Although the number R of first-level replicates should be at least 1000, it will often be adequate to take the number Q of second-order replicates of order 100: thus, around 100 000 bootstrap samples are needed in all. With today's fast computing, this can be quite feasible.

Chapter 5 of [2] gives fuller details of these bootstrap confidence-interval procedures, and describes other approaches.

Hypothesis Tests

Often a sample is used to test a null hypothesis about the population from which the sample was drawn – for example, we may want to test whether a correlation is zero, or if some mean response differs between groups of subjects. A standard approach is then to choose a test statistic T in such a way that large values of T give evidence against the null hypothesis, and to compute its value t_{obs} for the observed data. The strength of evidence against the hypothesis is given by the significance probability or P value p_{obs} , the probability of observing a value of T as large as or larger than t_{obs} if the hypothesis is true. That is, $p_{\text{obs}} = P_0(T \geq t_{\text{obs}})$, where P_0 represents a probability computed as if the null hypothesis were true. Small values of p_{obs} are regarded as evidence against the null hypothesis.

A significance probability involves the computation of the distribution of the test statistic under the null hypothesis. If this distribution cannot be obtained theoretically, then the bootstrap may be useful. A key step is to obtain an estimator $\hat{F}_0$ of the population distribution under the null hypothesis, F_0 . The bootstrap samples are then generated by sampling from $\hat{F}_0$, yielding R bootstrap replicates $T_1^*, \dots, T_R^*$ of T . The significance probability is estimated by

$$\hat{p}_{\text{obs}} = \frac{\{\text{number of } T^* \geq t_{\text{obs}}\} + 1}{R + 1},$$

where the +1s appear because t_{obs} is also a replicate under the null hypothesis, and $t_{\text{obs}} \geq t_{\text{obs}}$.

For bootstrap hypothesis testing to work, it is essential that the fitted distribution $\hat{F}_0$ satisfy the null hypothesis. This is rarely true of the empirical distribution function $\hat{F}$, which therefore cannot be used in the usual way. The construction of an appropriate $\hat{F}_0$ can entail restriction of $\hat{F}$ or the testing of a slightly different hypothesis. For example, the hypothesis of no correlation between `hand` and `dnan` could be tested by taking as test statistic $T = \hat{\theta}$, the sample correlation coefficient, but imposing this hypothesis would involve reweighting the points in Figure 1 in such a way that the correlation coefficient computed using the reweighted data would equal zero, followed by simulation of samples $y_1^*, \dots, y_n^*$ from the reweighted distribution. This would be complicated, and it is easier to test the stronger hypothesis of independence, under which any association between `hand` and `dnan` arises purely by chance. If so, then samples may be generated under the null hypothesis by independent bootstrap resampling separately from the univariate empirical distributions for `hand` and for `dnan`; see (a) of Figure 4, which shows that pair (`hand*`, `dnan*`) that were not observed in the original data may arise when sampling under the null hypothesis. Comparison of (b) of Figure 2 and (b) of Figure 4 shows that the distributions of correlation coefficients generated using the usual bootstrap and under the independence hypothesis are quite different.

The handedness data have correlation coefficient $t_{\text{obs}} = 0.509$, and 18 out of 9999 bootstrap samples generated under the hypothesis of independence gave values of T^* exceeding t_{obs} . Thus $\hat{p}_{\text{obs}} = 0.0019$, strong evidence of a positive relationship. A two-sided test could be performed by taking $T = |\hat{\theta}|$, yielding significance probability of about 0.004 for the null hypothesis that there is neither positive nor negative association between `hand` and `dnan`.

A parametric test that assumes that the underlying distribution is bivariate normal gives an appreciably smaller one-sided significance probability of .0007, but the inadequacy of the normality assumption implies that this test is less reliable than the bootstrap test.

Another simulation-based procedure often used to test independence is the permutation method (*see Permutation Based Inference*), under which the values of one of the variables are randomly permuted. The resulting significance probability is typically very close to that from the bootstrap test, because the

Figure 4 Bootstrap hypothesis test of independence of hand and dnan. (a) intersections of the grey lines indicate possible pairs (hand^* , dnan^*) when resampling values of hand and dnan independently with replacement. The numbers show the multiplicities of the sampled pairs for a particular bootstrap resample. (b) histogram of correlation coefficients generated under null hypothesis of independence. The vertical line shows the value of the correlation coefficient for the dataset, and the shaded part of the histogram corresponds to the significance probability

only difference between the resampling schemes is that permutation samples without replacement and the bootstrap samples with replacement. For the handedness data, the permutation test yields one-sided and two-sided significance probabilities of .002 and .003 respectively.

Owing to the difficulties involved in constructing a resampling distribution that satisfies the null hypothesis, it is common in practice to use confidence intervals to test hypotheses. A two-sided test of the null hypothesis that $\theta = \theta_0$ may be obtained by bootstrap resampling from the usual empirical distribution function $\hat{F}$ to compute a $100(1 - \alpha)\%$ confidence interval. If this does not contain θ_0 , we conclude that the significance probability is less than α . For one-sided tests, we use one-sided confidence intervals. This approach is most reliable when used with an approximately pivotal statistic but this can be hard to verify in practice. For the handedness data, the value $\theta_0 = 0$ lies outside the 95% BCa confidence interval, but within the 99% confidence interval, so we would conclude that the significance probability for a two-sided test is between .01 and .05. This is appreciably larger than found above, but still gives evidence of

a relationship between the two variables. Using the transformed Studentized interval, however, we get a P value of greater than .10, which contradicts this conclusion. In general, inverting a confidence interval in this way seems to be unreliable and is not advised.

Chapter 4 of [2] contains a more complete discussion of bootstrap hypothesis testing.

More Complex Models

The discussion above considers only the simple situation of random sampling, but many applications involve more complex statistical models, such as the linear regression model (*see Multiple Linear Regression*). Standard assumptions for this are that the mean response variable is a linear function of explanatory variables, and that deviations from this linear function have a normal distribution. Here the bootstrap can be applied to overcome potential nonnormality of the deviations, by using the data to estimate their distribution. The deviations are unobserved because the true line is unknown, but they can be estimated using residuals, which can then

be resampled. If $\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k$ are estimates of the linear model coefficients and $e_1^*, \dots, e_n^*$ is a bootstrap sample from the residuals $e_1, \dots, e_n$, then bootstrap responses y^* can be constructed as

$$y_i^* = \hat{\beta}_0 + \hat{\beta}_1 x_{1i} + \dots + \hat{\beta}_k x_{ki} + e_i^*, \quad i = 1, \dots, n.$$

The values of the explanatory variables in the bootstrap sample are the same as for the original sample, but the response variables vary. Since the matrix of explanatory variables remains the same, this method is particularly appropriate in designed experiments where the explanatory variables are set by the experimenter. It does however presuppose the validity of the linear model from which the coefficients and residuals are estimated.

An alternative procedure corresponding to our treatment of the data in Table 1 is to resample the vector observations $(y_i, x_{1i}, \dots, x_{ki})$. This may be appropriate when the explanatory variables are not fixed by the experimenter but may be treated as random. One potential drawback is that the design matrix of the resamples may be singular, or nearly so, and if so there will be difficulties in fitting the linear model to the bootstrap sample. These procedures generalize to the **analysis of variance**, the **generalized linear model**, and other regression models.

Extensions of the bootstrap to **survival analysis** and time series (see **Time Series Analysis**) have also been studied in the literature. The major difficulty in complex models lies in finding a resampling scheme that appropriately mimics how the data arose. A detailed discussion can be found in Chapters 3 and 6–8 of [2].

Computer Resources

Although the bootstrap is a general computer intensive method for nonparametric inference, it does not appear in all statistical software packages. Code for bootstrapping can be written in most packages, but this does require programming skills. The most comprehensive suite of code for bootstrapping is the `boot` library written by A. J. Canty for S-Plus, which can be downloaded from <http://statwww.epfl.ch/davison/BMA/library.html>. This code has also been made available as a package for R by B. D. Ripley and can be downloaded free from <http://cran.r-project.org> as part of the binary releases of

the R package. Another free package that can handle a limited range of statistics is David Howell's Resampling Statistics available from <http://www.uvm.edu/dhowell/StatPages/Resampling/Resampling.html>. S-Plus also has many features for the bootstrap and related methods. Some are part of the base software but most require the use of the S + Resample library, which can be downloaded from <http://www.insightful.com/downloads/libraries/>. The commercial package Resampling Stats is available as a stand-alone program or as an add-in for Excel or Matlab from <http://www.resample.com/>. Statistical analysis packages that include some bootstrap functionality are Systat, Stata, and SimStat. There are generally limits to the types of statistics that can be resampled in these packages but they may be useful for many common statistics (see **Software for Statistical Analyses**).

Literature

Thousands of papers and several books about the bootstrap have been published since it was formulated by Efron [3]. Useful books for the practitioner include [7], [1], and [6]. References [2] and [4] describe the ideas underlying the methods, with many further examples, while [5] and [8] contain more theoretical discussion. Any of these contains many further references, though [1] has a particularly full bibliography. The May 2003 issue of *Statistical Science* contains recent surveys of aspects of the research literature.

Box Plots

Of all the graphical novelties unleashed on a disbelieving world by the late **John Tukey** [3] under the banner of **exploratory data analysis (EDA)**, only **stem and leaf plots** and box plots seem to have stood the test of time. Box plots, or box and whisker plots, follows the spirit of EDA by using only robust components in their construction, that is, ones which minimize the effects of **outliers** or crude data simplifying schemes (see [2] and [4] for more details). Thus, the length of the box is the midspread (**interquartile range**), while the measure of location marked within the box is the **median**. The most common rule for determining the lengths of the whiskers emanating from the top and bottom of the box uses the midspread – specifically, the whiskers are extended to the largest and smallest values (called ‘adjacent’ values) lying within upper and lower limits (fences) defined by 1.5 times the midspread above and below the box. Most box plots also display outliers that are also defined by the midspread in that they are values in the sample or batch that lie above or below these upper and lower limits. Alternative rules extend the whiskers to the largest and smallest values in the sample, regardless of whether these might be outliers, in order to reveal additional distributional properties of the sample, for example, whether it is symmetric or skewed, and if so in which direction? The labeled display in Figure 1 below, using data from Minitab’s *Pulse1* data set, illustrates the basic box plot components and terminology.

Early versions of box and whisker plots did not use the upper and lower **quartiles** to define the box

Figure 1 One sample box plot with the major parts labeled

length, but used closely related measures, termed the upper and lower ‘hinges’ by Tukey [3]. These, like the median, represent natural folding points in an ordered sample. Other refinements included fences, which add structure to the areas beyond the upper and lower limits defined earlier, and notches with different angles cut into the sides of the box to represent the size of the sample’s 95% confidence interval about the median.

Tukey also recommended employing the *width* of the box plot to represent the sample size where one wants to compare samples of differing size. Unfortunately, the latter advice can lead to the analyst coming under the malign influence of the so-called *Wundt illusion* when eyeballing plots where the width and length of the box can vary simultaneously and independently. However, while few of these refinements have been incorporated into the major statistics packages, other novelties are on offer. For example, in Minitab, a **Confidence Interval** box can be substituted for the midspread box, and adjacent box plots linked by their medians to facilitate comparisons between them. Thus, box plots can yield a surprising amount of information about differences in the location, spread, and shape of the samples, and about the presence of outliers. Figure 2 is an example of a side by side display for comparing two samples. The data used for the plot is from Minitab’s *Pulse* dataset.

With multiple box plots, one can also compare the distributions and outlier proneness of the samples: this, in turn, provides the basis for a conservative informal graphical inference in that plots whose

Figure 2 Two sample box plots for comparing pulse after exercise for males and females

2 Box Plots

boxes do not overlap contain medians that are also different. A more precise version of the latter test is available with notched box plots, where the probability of rejecting the null hypothesis of true equal medians is 0.05 when the 95% notches just clear each other, provided that it can be assumed that the samples forming the comparison are roughly normally distributed, with approximately equal spreads (see [1] for more details).

Bradley–Terry Model

A paired comparison experiment involves several ‘judges’ comparing several ‘objects’. Each judge performs a number of paired comparisons, that is, considers a pair of the objects, and indicates which of the two is preferred. Bradley and Terry [3] present an example in which the objects are three types of pork roast, depending on the ingredients in the feed of the hogs (just corn, corn plus some peanut, corn plus much peanut). For each comparison, a judge was given two samples of pork roast from different feeds, and the judge indicated the preferred one. Each judge performed several paired comparisons. In a sports context, the objects would be the players (e.g., in tennis) or the teams (e.g., in baseball). There are no judges as such, but a comparison is a match or game, and the determination of which in a pair is preferred is based on who wins the match.

Models for such data would generally be based on the probabilities that Object i is preferred to Object j for each i, j . A fairly simple model would have the chance Object i is preferred to Object j be based on just the relative overall strength or popularity of the two objects. That is, there would be no particular interaction between objects. The notion of no interaction would imply that if Team A is likely to beat Team B, and Team B is likely to beat Team C, then Team A is even more likely to beat Team C. The Bradley–Terry model, sometimes called the Bradley–Terry–Luce model, is one popular method for explicitly exhibiting this lack of interaction. Each object i is assumed to have a positive measure of strength v_i , where the chance that Object i is preferred is

$$p_{ij} = P[\text{Object } i \text{ is preferred to Object } j] = \frac{v_i}{v_i + v_j}. \quad (1)$$

The model is thought to be first proposed by Zermelo [16], but Bradley and Terry [3] brought it into wide popularity among statistical practitioners. See [7] for an extensive bibliography, and the book [5], which covers other models as well.

It is often more convenient to work with odds than with probabilities (see **Odds and Odds Ratios**). If p

is the probability of an event, then the odds are

$$\text{Odds} = \frac{p}{1-p}, \quad \text{hence} \quad p = \frac{\text{Odds}}{1 + \text{Odds}}. \quad (2)$$

The Bradley–Terry probability in (1) then translates to

$$\begin{aligned} \text{Odds}_{ij} &= \text{Odds}[\text{Object } i \text{ is preferred to Object } j] \\ &= \frac{v_i}{v_j}. \end{aligned} \quad (3)$$

An approach to motivating this model follows. Imagine two tennis players, named A and B. The chance Player A has of winning a match against a typical opponent is $p_A = 0.80$, and the chance Player B has of winning against a typical opponent is $p_B = 0.65$. Without any other information, what would be a reasonable guess of the chance that Player A would beat Player B? It would be greater than 50%, because Player A is a better player than B, and would be less than 80%, because Player B is better than the typical player. But can we be more informative?

One approach is to set up a competition in which Player A has a coin with chance of heads being p_A , and Player B has a coin with chance of heads being p_B . The two players flip their coins simultaneously. If one is heads and one is tails, the player with the heads wins. If both are heads or both are tails, they flip again. They continue until a pair of flips determines a winner. The chance Player A wins this competition is the chance A flips heads given that there is a decision, that is, given that one of A and B flips heads and the other flips tails. Thus

$$p_{AB} = P[A \text{ beats } B] = \frac{p_A(1-p_B)}{p_A(1-p_B) + (1-p_A)p_B}. \quad (4)$$

With $p_A = 0.80$ and $p_B = 0.65$, we have $P[A \text{ beats } B] = 0.28/(0.28 + 0.13) = 0.6829$. That is, we guess that the chance A beats B is about 68%, which is at least plausible. The relationship between $P[A \text{ beats } B]$ and p_A, p_B in (4) is somewhat complicated. The formula can be simplified by looking at odds instead of probability. From (4),

$$\begin{aligned} \text{Odds}_{AB} &= \text{Odds}[A \text{ beats } B] \\ &= \frac{p_A(1-p_B)/(p_A(1-p_B) + (1-p_A)p_B)}{1 - p_A(1-p_B)/(p_A(1-p_B) + (1-p_A)p_B)} \end{aligned}$$

2 Bradley–Terry Model

$$\begin{aligned} &= \frac{p_A}{1 - p_A} \frac{1 - p_B}{p_B} \\ &= \frac{Odds_A}{Odds_B}, \end{aligned} \quad (5)$$

where $Odds_A$ is the odds player A beats a typical player. These odds are the Bradley–Terry odds (3), with v_A being identified with $Odds_A$. That is, the Bradley–Terry parameter v_i can be thought of as the odds Object i is preferred to a typical object.

Sections titled Luce’s Choice Axiom and Thurstone’s Scaling discuss additional motivations based on Luce’s Choice Axiom and Thurstonian choice models, respectively. The next section exhibits the use of the Bradley–Terry model in examples. The section titled Ties deals briefly with ties, and the section titled Calculating the Estimates has some remarks concerning calculation of estimates.

Modeling Paired Comparison Experiments

The basic Bradley–Terry model assumes that there are L objects, labeled $1, \dots, L$, Object i having associated parameter $v_i > 0$, and n independent comparisons between pairs of objects are performed. The chance that Object i is preferred to Object j when i and j are compared is given in (1). The data can be summarized by the counts n_{ij} , the number of paired comparisons in which i is preferred to j . The likelihood function (see **Maximum Likelihood Estimation**) is then

$$\begin{aligned} L(v_1, \dots, v_L; \{n_{ij} | i \neq j\}) &= \prod_{i \neq j} p_{ij}^{n_{ij}} \\ &= \prod_{i \neq j} \left(\frac{v_i}{v_i + v_j} \right)^{n_{ij}}. \end{aligned} \quad (6)$$

In the example comparing pork roasts in [3], let Object 1 be the feed with just corn, Object 2 the feed with corn and some peanut, and Object 3 the feed with corn and much peanut. Then the results from Judge I, who made five comparisons of each pair, are (from Table 4 in their paper)

Corn preferred to (Corn + Some peanut)	$n_{12} = 0$
(Corn + Some peanut) preferred to Corn	$n_{21} = 5$
Corn preferred to Corn + Much peanut	$n_{13} = 1$
(Corn + Much peanut) preferred to Corn	$n_{31} = 4$
(Corn + Some peanut) preferred to (Corn + Much peanut)	$n_{23} = 2$
(Corn + Much peanut) preferred to (Corn + Some peanut)	$n_{32} = 3$

(7)

The likelihood (6) in this case is

$$\begin{aligned} &\left(\frac{v_1}{v_1 + v_2} \right)^0 \left(\frac{v_2}{v_1 + v_2} \right)^5 \left(\frac{v_1}{v_1 + v_3} \right)^1 \\ &\times \left(\frac{v_3}{v_1 + v_3} \right)^4 \left(\frac{v_2}{v_2 + v_3} \right)^2 \left(\frac{v_3}{v_2 + v_3} \right)^3 \\ &= \frac{v_1 v_2^7 v_3^7}{(v_1 + v_2)^5 (v_1 + v_3)^5 (v_2 + v_3)^5}. \end{aligned} \quad (8)$$

Note that the numerator in (8) has parameter v_i raised to the total number of times Object i is preferred in any of the paired comparisons, and the denominator has for each pair i, j of objects the sum of their parameters $(v_i + v_j)$ raised to the total number of times those two objects are compared. That is, in general, the likelihood in (6) can be written

$$L(v_1, \dots, v_L; \{n_{ij} | i \neq j\}) = \frac{\prod_{i=1}^n v_i^{n_i}}{\prod_{i < j} (v_i + v_j)^{N_{ij}}}, \quad (9)$$

where

$$n_i = \sum_{j \neq i} n_{ij} \quad \text{and} \quad N_{ij} = n_{ij} + n_{ji}. \quad (10)$$

In fact, $(n_1, \dots, n_L)$ is a sufficient statistic for this model.

The parameters can be estimated using maximum likelihood (see section titled Calculating the Estimates for some computational approaches), but notice that these probabilities do not change if every v_i is multiplied by the same positive constant c , which means that the v_i ’s are not uniquely determined by the p_{ij} ’s. One usually places a constraint on the v_i ’s, for example, that $v_L = 1$, or that $v_1 + \dots + v_L = 1$.

I prefer scaling the v_i 's so that

$$\frac{1}{L} \sum_{i=1}^L \frac{v_i}{1+v_i} = \frac{1}{2}, \quad (11)$$

which means that v_i is the odds that Object i is preferred to a 'typical' ideal object, where the typical object has on an average a 50% chance of being preferred over the others.

Maximizing (8) subject to the constraint in (11) yields the estimates

$$\hat{v}_1 = 0.2166, \hat{v}_2 = \hat{v}_3 = 1.9496. \quad (12)$$

This judge likes some or much peanut equally, and any peanut substantially better than no peanut.

Bradley and Terry also present the results from another judge, Judge II, who again made five comparisons of each pair. Let m_{ij} be the number of times Judge II preferred Object i to Object j , and τ_1, τ_2, τ_3 be the corresponding Bradley–Terry parameters. One can imagine at least two models for the combined data of the two judges: (1) The judges have the same preferences, so that $v_1 = \tau_1, v_2 = \tau_2, v_3 = \tau_3$; (2) The judges may have different preferences, so that v_i does not necessarily equal τ_i . The likelihoods for the two models are

$$L_{\text{Same}} = \prod_{i \neq j} \left(\frac{v_i}{v_i + v_j} \right)^{n_{ij} + m_{ij}} \quad (13)$$

and

$$L_{\text{Different}} = \prod_{i \neq j} \left(\frac{v_i}{v_i + v_j} \right)^{n_{ij}} \left(\frac{\tau_i}{\tau_i + \tau_j} \right)^{m_{ij}}, \quad (14)$$

respectively.

The data for Judge II are

$$\begin{aligned} m_{12} &= 3, m_{21} = 2, m_{13} = 4, \\ m_{31} &= 1, m_{23} = 3, m_{32} = 2. \end{aligned} \quad (15)$$

In the second model (14), the estimates of the v_i 's are those in (12), and the estimate of the τ_i 's are

$$\hat{\tau}_1 = 1.7788, \hat{\tau}_2 = 1.0000, \hat{\tau}_3 = 0.5622. \quad (16)$$

On the basis of the estimates, Judge II appears to have distinctly different preferences than Judge I; Judge II prefers less peanut over more.

The question arises whether the apparent difference between the judges is statistically significant, which we address by testing the hypotheses

$$\begin{aligned} H_0: (v_1, v_2, v_3) &= (\tau_1, \tau_2, \tau_3) \quad \text{versus} \\ H_A: (v_1, v_2, v_3) &\neq (\tau_1, \tau_2, \tau_3). \end{aligned} \quad (17)$$

The likelihood ratio test (*see* **Maximum Likelihood Estimation**) uses the statistic

$$W = 2[\log(L_{\text{Different}}) - \log(L_{\text{Same}})], \quad (18)$$

where in $L_{\text{Different}}$ we replace the parameters with their estimates from (12) and (16), and in L_{Same} with the maximum likelihood estimates from (13), which are

$$(\hat{v}_1, \hat{v}_2, \hat{v}_3) = (\hat{\tau}_1, \hat{\tau}_2, \hat{\tau}_3) = (0.7622, 1.3120, 1.0000). \quad (19)$$

Under the null hypothesis that the two judges have the same preference structure, W will be approximately χ^2_2 . The degrees of freedom here are the difference between the number of free parameters in the alternative hypothesis, which is 4 because there are six parameters but two constraints, and the null hypothesis, which is 2. In general, if there are L objects and M judges, then testing whether all M judges have the same preferences uses $(L-1) \times (M-1)$ degrees of freedom.

For these data, $W = 8.5002$, which yields an approximate P value of 0.014. Thus, it appears that indeed the two judges have different preferences.

Example: Home and Away Games

Agresti ([1], pages 437–438) applies the Bradley–Terry model to the 1987 performance of the seven baseball teams in the American League Eastern Division. Each pair of teams played 13 games. In the simplest Bradley–Terry model, each team has its v_i . The estimates are given in the first column of Table 1.

Each game is played in the home ballpark of one of the teams, and there is often an advantage to playing at home. A more complex model supposes that each team has two parameters, one for when it is playing at home and one for when it is playing away. Thus there are 14 parameters, v_i^{Home} and v_i^{Away} for each $i = 1, \dots, L = 7$, with one constraint as

4 Bradley–Terry Model

Table 1 Estimated odds for the baseball teams

	Simple	Home	Away	Effect	Neutral	Home	Away
Milwaukee	1.6824	2.1531	1.3367	1.6107	1.6970	1.9739	1.4590
Detroit	1.4554	1.8827	1.1713	1.6074	1.4691	1.7088	1.2630
Toronto	1.2628	1.0419	1.5213	0.6849	1.2667	1.4734	1.0890
New York	1.2050	1.3420	1.0997	1.2203	1.2100	1.4074	1.0403
Boston	1.0477	1.8104	0.6108	2.9639	1.0545	1.2266	0.9066
Cleveland	0.6857	0.8066	0.5714	1.4115	0.6798	0.7907	0.5844
Baltimore	0.3461	0.3145	0.3688	0.8526	0.3360	0.3908	0.2889

usual. In this case, not every pair is observed, that is, Milwaukee cannot be the home team and away team in the same game. That fact does not present a problem in fitting the model, though. The second and third columns in Table 1 give the estimated home and away odds for each team in this model. The ‘Effect’ column is the ratio of the home odds to the away odds, and estimates the effect of being at home versus away for each team. That is, it is the odds the home team would win in the imaginary case that the same team was the home and away team. For most teams, the odds of winning are better at home than away, especially for Boston, although for Toronto and Baltimore the reverse is true.

To test whether there is a home/away effect, one can perform the likelihood ratio test between the two models. The $W = 10.086$ on 7 degrees of freedom (7 because the simple model has $7 - 1 = 6$ free parameters, and the more complicated model has $14 - 1 = 13$). The approximate P value is 0.18, so it appears that the simpler model is not rejected.

Agresti considers a model between the two, where it is assumed that the home/away effect is the same for each team. The parameter v_i can be thought of as the odds of team i winning at a neutral site, and a new parameter θ is introduced that is related to the home/away effect, where

$$v_i^{\text{Home}} = \theta v_i \quad \text{and} \quad v_i^{\text{Away}} = \frac{v_i}{\theta}. \quad (20)$$

Then the odds that team i beats team j when the game is played at team i ’s home is

$$\text{Odds}(i \text{ at home beats } j) = \theta^2 \frac{v_i}{v_j}, \quad (21)$$

and the home/away effect is the same for each team, that is,

$$\text{Effect}(\text{team } i) = \frac{v_i^{\text{Home}}}{v_i^{\text{Away}}} = \frac{\theta v_i}{v_i / \theta} = \theta^2. \quad (22)$$

Table 1 contains the estimated v_i ’s in the ‘Neutral’ column. Notice that these values are very close to the estimates in the simple model. The estimate of θ is 1.1631, so that the effect for each team is $(1.1631)^2 = 1.3529$. The last two columns in the table give the estimated v_i^{Home} ’s and v_i^{Away} ’s. This model is a ‘smoothed’ version of the second model.

To test this model versus the simple model, we have $W = 5.41$. There is 1 degree of freedom here, because the only additional parameter is θ . The P value is then 0.02, which is reasonably statistically significant, suggesting that there is indeed a home/away effect. One can also test the last two models, which yields $W = 4.676$ on $13 - 7 = 6$ degrees of freedom, which is clearly not statistically significant. Thus, there is no evidence that the home/away effect differs among the teams.

Luce’s Choice Axiom

In the seminal book *Individual Choice Behavior* [10], Luce proposed an axiom to govern models for choosing one element among any given subset of elements. The Axiom is one approach to specifying ‘lack of interaction’ between objects when choosing from subsets of them. That is, the relative preference between two objects is independent of which other objects are among the choices. This idea is known as ‘independence from irrelevant alternatives.’

To be precise, let $\mathcal{O} = \{1, \dots, L\}$ be the complete set of objects under consideration and T be any subset of $\mathcal{O}$. Then, for Object $i \in T$, denote

$$P_T(i) = P[i \text{ is most preferred among } T]. \quad (23)$$

The special case of a paired comparison has T consisting of just two elements, for example,

$$P_{\{i,j\}}(i) = P[i \text{ is preferred to } j]. \quad (24)$$

Luce's Axiom uses the notation that for $S \subset T$,

$$\begin{aligned} P_T(S) &= P[\text{The most preferred object among } T \text{ is in } S] \\ &= \sum_{i \in S} P_T(i). \end{aligned} \quad (25)$$

The axiom follows.

Luce's Choice Axiom. For any $T \subset \mathcal{O}$,

$$(i) \quad \text{If } P_{\{a,b\}}(a) \neq 0 \text{ for all } a, b \in T, \text{ then for } i \in S \subset T, \quad P_T(i) = P_S(i)P_T(S); \quad (26)$$

$$(ii) \quad \text{If } P_{\{a,b\}}(a) = 0 \text{ for some } a, b \in T, \text{ then if } i \in T, i \neq a, \quad P_T(i) = P_{T-\{a\}}(i). \quad (27)$$

The essence of the Axiom can be best understood when $P_{\{a,b\}}(a) \neq 0$ for all $a, b \in \mathcal{O}$, that is, when in any paired comparison, there is a positive chance that either object is preferred. Then equation (26) is operational for all $i \in S \subset T$.

For an example, suppose $\mathcal{O} = \{\text{Coke, Pepsi, 7-up, Sprite}\}$. The axiom applied to $T = \mathcal{O}$, $S = \{\text{Coke, Pepsi}\}$ (the colas) and $i = \text{Coke}$ is

$$\begin{aligned} &P(\text{Coke is the favorite among all four}) \\ &= P(\text{Coke is preferred to Pepsi}) \\ &\quad \times P(\text{A cola is chosen as the favorite} \\ &\quad \text{among all four}). \end{aligned} \quad (28)$$

Thus, the choosing of the favorite can be decomposed into a two-stage process, where the choosing of Coke as the favorite starts by choosing colas over noncolas, then Coke as the favorite cola.

There are many implications of the Axiom. One is a precise formulation of the independence from irrelevant alternatives:

$$\frac{P_{\{i,j\}}(i)}{P_{\{i,j\}}(j)} = \frac{P_S(i)}{P_S(j)} \quad (29)$$

for any subset S that contains i and j . That is, the relative preference of i and j remains the same no

matter which, if any, other objects are available. In the soft drink example, this independence implies, in particular, that

$$\begin{aligned} \frac{P_{\{\text{Coke}, 7\text{-up}\}}(\text{Coke})}{P_{\{\text{Coke}, 7\text{-up}\}}(7\text{-up})} &= \frac{P_{\{\text{Coke}, 7\text{-up}, \text{Sprite}\}}(\text{Coke})}{P_{\{\text{Coke}, 7\text{-up}, \text{Sprite}\}}(7\text{-up})} \\ &= \frac{P_{\mathcal{O}}(\text{Coke})}{P_{\mathcal{O}}(7\text{-up})}. \end{aligned} \quad (30)$$

The main implication is given in the next Theorem, which is Theorem 3 in [10].

Luce's Theorem. Assume that the Choice Axiom holds, and that $P_{\{a,b\}}(a) \neq 0$ for all $a, b \in \mathcal{O}$. Then, there exists a positive finite number for each object, say v_i for Object i , such that for any $i \in S \subset \mathcal{O}$,

$$P_S(i) = \frac{v_i}{\sum_{j \in S} v_j}. \quad (31)$$

The interest in this paper is primarily paired comparison, and we can see that for paired comparisons, the Luce Choice Axiom with $S = \{i, j\}$ leads to the Bradley–Terry model (1), as long as the v_i 's are strictly between 0 and ∞ .

Thurstone's Scaling

Scaling models in preference data is addressed fully in [2], but here we will briefly connect the two. Thurstone [14] models general preference experiments by assuming that a given judge has a one-dimensional response to each object. For example, in comparing pork roasts, the response may be based on tenderness, or in the soft drinks, the response may be based on sweetness, or caffeine stimulation. Letting Z_a be the response to Object a , the probability of preferring i among those in subset T (which contains i) is given by

$$\begin{aligned} P_T(i) &= P[i \text{ is most preferred among } T] \\ &= P[Z_i > Z_j, \quad j \in T - \{i\}]. \end{aligned} \quad (32)$$

That is, the preferred object is that which engenders the largest response.

6 Bradley–Terry Model

Thurstone gives several models for the responses $(Z_1, \dots, Z_L)$ based on the Normal distribution. Daniels [4] looks at cases in which the Z 's are independent and from a location-family model with possibly different location parameters; [8] and [13] used gamma distributions. A question is whether any such Thurstonian model would satisfy Luce's Choice Axiom. The answer, given by Luce and Suppes in [11], who attribute the result to Holman and Marley, is the Gumbel distribution. That is, the Z_i 's are independent with density

$$f_{\mu_i}(z_i) = \exp(-(z_i - \mu_i)) \exp(-\exp(-(z_i - \mu_i))), \\ -\infty < z_i < \infty, \quad (33)$$

where the μ_i measures the typical strength of the response for Object i . Then the Thurstonian choice probabilities from (32) coincide with the model (31) with $v_i = \exp(\mu_i)$. Yellott [15] in fact shows that the Gumbel is the only distribution that will satisfy the Axiom when there are three or more objects.

Ties

It is possible that paired comparisons result in no preference, for example, in soccer, it is not unusual for a game to end in a tie, or people may not be able to express a preference between two colas. Particular parameterizations of the paired comparisons when extending the Bradley–Terry parameters to the case of ties are proposed in [12] and [6]. Rao and Kupper [12] add the parameter θ , and set

$$P[\text{Object } i \text{ is preferred to Object } j] = \frac{v_i}{v_i + \theta v_j}. \quad (34)$$

In this case, the chance of a tie when i and j are compared is

$$1 - \frac{v_i}{v_i + \theta v_j} - \frac{v_j}{v_j + \theta v_i} = \frac{\theta(v_i + v_j)}{(v_i + \theta v_j)(v_j + \theta v_i)}. \quad (35)$$

Davidson [6] adds positive c_{ij} 's so that the probability that Object i is preferred to Object j is

$v_i/(v_i + v_j + c_{ij})$. He suggests taking $c_{ij} = c\sqrt{v_i v_j}$ for some $c > 0$, so that

$$P[\text{Object } i \text{ is preferred to Object } j] \\ = \frac{v_i}{v_i + v_j + c\sqrt{v_i v_j}} \quad (36)$$

and

$$P[\text{Object } i \text{ and Object } j \text{ are tied}] \\ = \frac{c\sqrt{v_i v_j}}{v_i + v_j + c\sqrt{v_i v_j}}. \quad (37)$$

Davidson's suggestion may be slightly more pleasing than (34) because the v_i 's have the same meaning as before conditional on there being a preference, that is,

$$P[\text{Object } i \text{ is preferred to Object } j | \\ \text{Object } i \text{ and Object } j \text{ are not tied}] \\ = \frac{v_i}{v_i + v_j}. \quad (38)$$

Calculating the Estimates

In the Bradley–Terry model with likelihood as in (6), the expected number of times Object i is preferred equals

$$E[n_i] = E \left[\sum_{j \neq i} n_{ij} \right] = \sum_{j \neq i} N_{ij} \frac{v_i}{v_i + v_j}. \quad (39)$$

where n_i is the total number of times Object i is preferred, and N_{ij} is the number of times Objects i and j are compared, as in (10). The **maximum likelihood estimates** of the parameters are those that equate the n_i 's with their expected values, that is, they satisfy

$$n_i = \sum_{j \neq i} N_{ij} \frac{\hat{v}_i}{\hat{v}_i + \hat{v}_j}. \quad (40)$$

Rewriting (ignore the superscripts for the moment),

$$\hat{v}_i^{(k+1)} = \frac{n_i}{\sum_{j \neq i} N_{ij} / (\hat{v}_i^{(k)} + \hat{v}_j^{(k)})}, \quad (41)$$

This equation is the basis of an iterative method for finding the estimates. Starting with a guess $(\hat{v}_1^{(0)}, \dots, \hat{v}_L^{(0)})$ of the estimates, a sequence $(\hat{v}_1^{(k)}, \dots, \hat{v}_L^{(k)})$, $k = 0, 1, \dots$, is produced where the $(k + 1)$ st vector is obtained from the k th vector via (41). After finding the new estimates, renormalize them, for example, divide them by the last one, so that the last is then 1. Zermelo [16] first proposed this procedure, and a number of authors have considered it and variations since. Rao and Kupper [12] and Davidson [6] give modifications for the models with ties presented in the section titled Ties. Under certain conditions, this sequence of estimates will converge to the maximum likelihood estimates. In particular, if one object is always preferred, the maximum likelihood estimate does not exist, and the algorithm will fail. See [9] for a thorough and systematic presentation of these methods and their properties.

An alternative approach is given in [1], pages 436–438, that exhibits the Bradley–Terry model, including the one in (20), as a logistic regression model. Thus widely available software can be used to fit the model. The idea is to note that the data can be thought of as $(L/2)$ independent binomial random variables,

$$n_{ij} \sim \text{Binomial}(N_{ij}, p_{ij}), \quad \text{for } i < j. \quad (42)$$

Then under (1) and (3),

$$\log(\text{Odds}_{ij}) = \log(v_i) - \log(v_j) = \beta_i - \beta_j, \quad (43)$$

that is, the $\log(\text{Odds})$ is a linear function of the parameters $\beta_i (= \log(v_i))$'s. The constraint that $v_L = 1$ means $\beta_L = 0$. See [1] for further details.

Breslow–Day Statistic

The **case-control study** is often conducted to evaluate the association between exposure and disease in epidemiology. In order to control for potential confounders, one can stratify the data into a series of 2×2 tables, with one table for each value of the potential confounder. Table 1 shows the data in the i th of a series of 2×2 tables, for $i = 1, \dots, K$. If the association between exposure and disease is constant over strata, then Mantel–Haenszel estimator (see **Mantel–Haenszel Methods**), then $\hat{\psi}_{MH} = \sum_i R_i / \sum_i S_i$, where $R_i = a_i d_i / N_i$ and $S_i = b_i c_i / N_i$, is usually used to estimate the common odds ratio, ψ .

Breslow and Day [2, p.142] propose the statistic

$$Z^2(\hat{\psi}) = \sum_{i=1}^K \frac{a_i - \hat{e}_i(\hat{\psi})}{\hat{v}_i(\hat{\psi})} \quad (1)$$

for testing the homogeneity of the K odds ratios against the global alternative of heterogeneity. Here, $\hat{\psi}$ is the unconditional **maximum likelihood estimator** of ψ , $\hat{e}_i(\psi)$, the asymptotic expected number of exposed cases, is the appropriate solution to the quadratic equation

$$\frac{\hat{e}_i(\psi)[N_{0i} - t_i + \hat{e}_i(\psi)]}{[N_{1i} - \hat{e}_i(\psi)][t_i - \hat{e}_i(\psi)]} = \psi, \quad (2)$$

and $\hat{v}_i(\psi)$, the asymptotic variance of exposed cases, is given by

$$\hat{v}_i(\psi) = \left[\frac{1}{\hat{e}_i(\psi)} + \frac{1}{N_{0i} - t_i + \hat{e}_i(\psi)} + \frac{1}{N_{1i} - \hat{e}_i(\psi)} + \frac{1}{t_i - \hat{e}_i(\psi)} \right]^{-1}. \quad (3)$$

When the number of strata, K , is small and each table has large frequencies, $Z^2(\hat{\psi})$ is asymptotically (as each N_i gets large) distributed as χ^2 with

$K - 1$ degrees of freedom, under the homogeneity hypothesis.

Breslow and Day [2, p. 142] also suggest that a valid test can be based on $Z^2(\hat{\psi}_{MH})$. However, since $\hat{\psi}_{MH}$ is not efficient, Tarone [4] and Breslow [1] noted that $Z^2(\hat{\psi}_{MH})$ is stochastically larger than a χ^2 random variable (see **Catalogue of Probability Density Functions**) under the homogeneity hypothesis. The correct form for the test proposed by Tarone [4] is

$$Y^2(\hat{\psi}_{MH}) = \sum_{i=1}^K \frac{a_i - \hat{e}_i(\hat{\psi}_{MH})}{\hat{v}_i(\hat{\psi}_{MH})} - \frac{\sum_i a_i - \sum_i \hat{e}_i(\hat{\psi}_{MH})}{\sum_i \hat{v}_i(\hat{\psi}_{MH})}. \quad (4)$$

When the number of strata is small and each table has large frequencies, $Y^2(\hat{\psi}_{MH})$ follows an approximate χ^2 distribution on $K - 1$ degrees of freedom, under the homogeneity hypothesis. As noted by Breslow [1], since $\hat{\psi}_{MH}$ is nearly efficient, the correction term in $Y^2(\hat{\psi}_{MH})$ (the second term on the right-hand side of (4)) is frequently negligible. Because of the computational simplicity of $\hat{\psi}_{MH}$, the test statistic $Y^2(\hat{\psi}_{MH})$ is recommended in practice.

Shown in Table 2 is an example with $K = 2$ from Tarone [4] and Halperin et al. [3]. For this example,

$$\hat{\psi}_{MH} = 10.6317, \hat{e}_1(\hat{\psi}_{MH}) = 179.7951,$$

$$\hat{e}_2(\hat{\psi}_{MH}) = 765.2785,$$

$$\hat{v}_1(\hat{\psi}_{MH}) = 17.4537, \hat{v}_2(\hat{\psi}_{MH}) = 89.8137. \quad (5)$$

It follows that $Y^2(\hat{\psi}_{MH}) = 8.33$. Since $Y^2(\hat{\psi}_{MH})$ is asymptotically χ_1^2 under the null hypothesis of a common odds ratio, there is evidence of heterogeneity (P value = 0.0039). Note that the correction term in $Y^2(\hat{\psi}_{MH})$ is -0.24 .

Table 1 The i th of a series of 2×2 tables

Exposure	Observed frequencies		
	Case	Control	Total
Exposed	a_i	b_i	t_i
Unexposed	c_i	d_i	$N_i - t_i$
Total	N_{1i}	N_{0i}	N_i

Table 2 Example of $2 \times 2 \times 2$ table

Exposure	The 1st table			The 2nd table		
	Case	Control	Total	Case	Control	Total
Exposed	190	810	1000	750	250	1000
Unexposed	10	990	1000	250	750	1000
Total	200	1800	2000	1000	1000	2000

Brown, William

Born: December 5, 1881, in Sussex, England.

Died: May 17, 1952, in Berkshire, England.

Putting William Brown into any particular pigeonhole is difficult: he was psychologist, psychiatrist, administrator, and, chiefly in the early days of his career, psychometrician.

The son of a schoolmaster, Brown attended a local school until winning a scholarship to Christ's College, Oxford in 1899. He spent the next six years in Oxford taking Mathematical Moderations in 1902, Final Honours in Natural Science (Physiology) in 1904, and finally *Literae Humaniores* with psychology as a special subject the following year. After a spell in Germany as a John Locke Scholar in Mental Philosophy during 1906, he returned to England to continue medical and statistical studies in London. By 1909 Brown had obtained a lectureship in psychology at King's College, London, followed by readership in 1914, the same year that he qualified in medicine. Meanwhile, he had been working in **Karl Pearson's** Biometrical Laboratory at University College London, earning a DSc and the coveted Carpenter medal in 1910 for a pioneering examination of how Pearson's correlational methods could be applied to psychological measurement.

The following year, Brown published *The Essentials of Mental Measurement* [1] based partly on his DSc work. This book, with its criticisms (almost certainly encouraged by Pearson) of Spearman's two factor theory of mental ability, propelled Brown into the center of a long running dispute with **Spearman**, while at the same time landing himself an ally in **Godfrey Thomson**, who would become an even more implacable critic of Spearman's notions. Subsequent editions of Brown's book were coauthored with Thomson, although it is quite clear that Thomson took the major role in the revisions and their renewed attacks on Spearman. While Thomson and Spearman were never reconciled, Brown eventually recanted in 1932 [3], very publicly going over to Spearman's side.

Brown's experiences as an RAMC officer treating shell-shock victims during the First World

War had shifted him ever more toward psychiatry and psychotherapy, and, once back in civilian life, he began to acquire more medical qualifications (DM in 1918, then MRCP and FRCP in 1921 and 1930, respectively). In 1921 he resigned his post in King's College, returning to Oxford to the Wilde Readership in Mental Philosophy. By the late 1920s, Brown was somehow juggling his work in Oxford, a clinical practice that included appointments as a psychotherapist at King's College and Bethlem Royal Hospitals, and writing prolifically on psychiatry and psychotherapy as well as making the occasional foray into psychometrics. Brown also played a significant role in establishing the Institute of Experimental Psychology in Oxford and was its first Director from 1936 to 1945.

After retiring in 1946, Brown continued with his writing and also remained active in other academic areas, for instance, serving as President of the British Psychological Society for 1951 to 1952. According to Godfrey Thomson, only a few weeks before his death in 1952, Brown was intent on making a return to the psychometric work that had launched him into prominence within the psychological establishment more than 40 years earlier.

What can we say of William Brown's legacy to psychological statistics? His criticism of Spearman's radical notions about mental ability certainly stirred up debate within British psychology and brought Godfrey Thomson into the emerging factor analysis arena. But we remember him chiefly for the Spearman–Brown coefficient (or prophesy formula) for determining the effect of test length on reliability. Unlike certain other cases, such as Spearman's rank correlation, exactly who should be credited with this particular measure is quite clear: in back-to-back articles published in 1910, we find the coefficient set out in a general form by Spearman [5] and then, in almost the same way as it is commonly used today, by Brown [2] (see [4]).

Bubble Plot

The simple xy **scatterplot** has been in use since at least the eighteenth century and is the primary data-analytic tool for assessing the relationship between a pair of continuous variables. But the basic scatterplot can only accommodate two variables, and there have been various suggestions as to how it might be enhanced to display the values of further variables. The simplest of these suggestions is perhaps a graphic generally known as a *bubble plot*. Here, two variables are used in the normal way to construct a scatterplot, and the values of a third variable are represented by circles with radii proportional to these values, centered on the appropriate point in the underlying scatterplot. Figure 1 shows an example of a bubble plot for the chest, hips, and waist measurements (in inches) of 20 individuals.

Bubble plots are often a useful supplement to the basic scatterplot, although, when large numbers of observations are plotted, the diagram can quickly

Figure 1 Bubble plot of hip, chest, and waist measurement; the last is represented by the radii of the circles

become difficult to read. In such cases, a **three-dimensional scatterplot** or a **scatterplot matrix** may be a better solution.

Burt, Cyril Lodowic

Born: March 3, 1883, in Stratford-upon-Avon.

Died: October 10, 1971, in London.

Cyril Burt was the son of a house-physician at Westminster Hospital and could trace his lineage through his father's mother to Newton's mathematical tutor at Cambridge, Sir Isaac Barrow. As a schoolboy, Burt first attended King's School, Warwick, and then in 1895 Christ's Hospital School in London as a boarder. He studied at Jesus College, Oxford, graduating with a degree in classics and philosophy. After completing his degree, Burt traveled to the University of Würzburg in Germany to study psychology under Oswald Külpe, and then returned to Oxford to become the John Locke scholar in mental philosophy.

In 1908, Burt became lecturer in experimental psychology at the University of Liverpool. It was here that his long research career began with a study comparing the intelligence of boys enrolled in an elite preparatory school with the intelligence of boys attending a regular school. Using measures such as mirror drawing that were unlikely to have been learnt during the student's lifetime, Burt showed that the prep school boys scored higher than the boys from the regular school and concluded that they had more innate intelligence. In addition, he noted that the fathers of the prep school students were more successful than the fathers of the other boys, a finding he interpreted as meaning that the prep school boys had benefited from their fathers' superior genetic endowments [1]. Burt, however, did not believe that 100% of intelligence is inherited and acknowledged that environmental influences are also important.

In 1913, Burt became Chief Psychologist for the London County Council and was responsible for the administration and interpretation of mental tests in London's schools. During this time, he developed new tests [2], a special school for the handicapped, and founded child guidance clinics. After twenty years of working for the LCC, Burt took up the Chair of Psychology at University College, London, recently vacated by **Charles Spearman**, where he remained until his retirement in 1950. Early in his career, Burt had worked with Spearman on various

aspects of intelligence and **factor analysis**, clearly invented by Spearman in 1904 [9], although this did not prevent Burt trying to claim the technique as his own later in his life (see both **History of Factor Analyses** entries).

Burt believed that intelligence levels were largely fixed by the age of 11, and so were accurately measurable by standard tests given at that age. On the basis of this belief, he became one of several influential voices that helped introduce the so-called eleven plus examination system in Great Britain, under which all 11-year-olds were given a series of academic and intelligence tests, the results of which determined their schooling for the next 5 to 7 years. And partly for this work, Burt, in 1946, became the first psychologist to be knighted, the Labour Government of the day bestowing the honor for his work on psychological testing and for making educational opportunities more widely available. Whether all those school children whose lives were adversely affected by the result of an examination taken at 11 would agree that the 11+ really made 'educational opportunities more widely available', is perhaps debatable.

In his working lifetime, Burt was one of the most respected and honored psychologists of the twentieth century. Indeed, according to Hans Eysenck in the obituary of Burt he wrote for *The British Journal of Mathematical and Statistical Psychology* [3], Sir Cyril Burt was 'one of England's outstanding psychologists'. But during his long retirement, he published over 200 articles, amongst them several papers that buttressed his hereditarian claim for intelligence by citing very high correlations between IQ scores of identical twins raised apart; according to Burt, these twins were separated in early childhood and raised in different socioeconomic conditions. Burt's study stood out among all others because he had found 53 pairs of such twins, more than twice the total of any previous attempt. Burt's methodology was generously and largely uncritically praised by some other academic psychologists, for example, Hans Eysenck and Arthur Jensen, but after Burt's death, closer scrutiny of his work by Kamin [7, 8] suggested at the best inexcusable carelessness and at worst conscious fraud and fakery. Kamin noticed, for example, that while Burt had increased his sample of twins from fewer than 20 to more than 50 in a series of publications, the average correlation between pairs for IQ remained

unchanged to the third decimal place. This statistically implausible result, allied to Burt's 'missing' coauthors, and a relatively random distribution of Burt's twins to families from various socioeconomic strata, led many to the uncomfortable conclusion that Burt may have fraudulently manufactured the data to support his belief that intelligence is largely inherited. This conclusion is supported in the biography of Burt published in 1979 [5] despite Hearnshaw's great respect for Burt and his initial skepticism about the accusations being made. Later accounts of Burt's work [4, 6] claim that the case for fraud is not proven and that Burt's critics are guilty of selective reporting. Whatever the truth of the matter, the last sentence of Eysenck's obituary of Burt now has a somewhat sad and ironic ring

'...as the first editor of this Journal (BJMSP) ... he set a very high standard of critical appraisal... This critical faculty combined with his outstanding originality, his great insight and his profound mathematical knowledge, makes him a truly great psychologist: his place in the history books of our science is assured.'

Bush, Robert R

Born: July 20, 1920, in Albion, Michigan.

Died: January 4, 1972, New York City.

Robert R. Bush first studied electrical engineering at Michigan State University and then physics at Princeton University, receiving a Ph.D. in 1949. A NRC/SSRC two-year post doc for natural scientists to study social science took him to Harvard's Department of Social Relations under the tutelage of statistician Frederick Mosteller. After first publishing a chapter on statistics for social scientists [5], a research project ensued on the statistical modeling of learning [3]. Their basic idea was that an individual selecting among finitely many alternatives on trial i is characterized by a vector of probabilities $\vec{p}_i$. Following a choice, reinforcement r occurs that is represented by a Markov process (see **Markov Chains**) with $\vec{p}_{i+1} = Q_r \circ \vec{p}_i$, where Q_r is a vector operator. They restricted attention to linear operators; others explored nonlinear ones as well. Bush focused on comparing various models and carrying out experiments to test them (see [1], [2] and [4]). By the mid-1960s, his (and psychology's) interest in such modeling waned. Mosteller, Galanter, and Luce speculate about four underlying reasons: (a) the empirical defeat of the gradual learning models by the all-or-none models developed by the mathematical psychology group at Stanford University; (b) the inability to arrive at a sensible account of the strong resistance to extinction in the face of partial reinforcement; (c) not finding a good way to partition the parameters of the model into aspects attributable to the individual, which should be invariant over experimental designs, and those attributable to the boundary conditions of the design; and (d) the paradigm shift to information processing and memory models [6]. (Note that this obituary describes Bush's career and research in considerable detail and lists all of his papers). Nonetheless, his modeling work influenced others, leading to the excellent synthesis by Norman [7], the important conditioning model of Rescorla and Wagner [8], several attempts to account for sequential effects in signal detection in terms of adjustments of the response criterion, and in a variety of other learning situations to this day arising in several fields: computer modeling, neural networks, and sociology.

In addition to his research, Bush was a superb and devoted teacher, with a number of Ph.D. students at major universities, and a very gifted administrator. During the 1950s, he helped organize and lead a series of summer workshops, mainly at Stanford. These led to recruiting young scientists, much research, several books, and the *Journal of Mathematical Psychology*. In 1956, he became an associate professor of applied mathematics at the New York School of Social Work. During that period, he, Galanter, and Luce met many weekends to carry out research, and they spawned the unlikely idea of his becoming chair of psychology at the University of Pennsylvania, one of the oldest such departments. Adventuresome administrators at Penn decided that a radical change was needed. Their gamble was justified by Bush's creating a powerful department which, to this day, has remained excellent. His success was so great that many expected he would move up the administrative ladder, but the necessary ceremonial aspects were anathema to him. Instead, in 1968, he became chair at Columbia. This move was motivated, in part, by his passion for ballet, especially the American Ballet Theater to which he devoted his money and administrative talents as a fund-raiser. The four years in New York, until his death, were a mixture of frustration at administrative indecision and deteriorating health.

Calculating Covariance

Covariance captures the extent to which two variables vary together in some systematic way, or whether variance in one variable is associated with variance in another variable. A sample covariance between variable X and variable Y (noted as COV_{xy} or s_{xy}) is an estimate of the population parameter σ_{xy} , and is defined mathematically as:

$$s_{xy} = \frac{\sum (X - \bar{X})(Y - \bar{Y})}{N - 1} = \frac{\sum xy}{N - 1} \quad (1)$$

Where $\bar{X}$ is the sample mean on X , $\bar{Y}$ is the sample mean on Y , $\sum xy$ is the sum of the cross products deviations of pairs of X and Y scores from their respective means (also known as the *sum of cross products*), and N is the sample size. Covariance values can be positive, negative, or zero. A positive covariance indicates that higher scores on X are paired with higher scores in Y , whereas a negative covariance indicates that scores on X are paired with lower scores on Y . When a covariance is equal to zero, X and Y are not linearly associated with each other.

The covariance is similar conceptually to the correlation coefficient (r), and in fact the two indices are perfectly and linearly correlated. It can be shown that the highest possible covariance value for variables X and Y is obtained when X and Y are perfectly correlated (i.e., correlated at -1.0 or $+1.0$) [1]. However, the covariance is scale-dependent, in that its value is heavily dependent on the unit of measurement used for X and Y . In contrast, the correlation coefficient is a standardized covariance and can vary between -1.0 and $+1.0$. Everything else being equal, the same correlation between X and Y will be represented by a larger covariance value when (a) the units of measurement for X and Y are larger, and (b) the variances of X and Y are larger. Thus, the covariance can indicate whether X and Y are correlated in a positive or negative way, but it is not very useful as an indicator of the strength of association between X and Y .

Campbell, Donald T

Born: November 20, 1916, in Michigan, USA.

Died: May 5, 1996, in Pennsylvania, USA.

'It is the fate of rebels to found new orthodoxies', so begins one of Bertrand Russell's *Nightmares of Eminent Persons*. And, so he might have added, it is also the fate of the holders of such orthodoxies, particularly if they stay active and high profile long enough, to be challenged in their turn by a new generation of rebels. The social theorist Donald T. Campbell is a prime example of this cyclical rule in that he initially made his name by aligning himself with the 'social physics' form of positivism and empirical realism at a time when hardly any of the social sciences employed such hard-nosed experimental and quantitative moves, then saw his new approach flourish in social psychology from the 1950s to the early 1970s (helped in no small way by Campbell's own efforts), only to be overtaken by the relativistic and postpositive backlash whose intellectual form had been sketched out in Thomas Kuhn's 1962 poetic masterpiece, *The Structure of Scientific Revolutions*. There is, however, the possibility of an even more intriguing (if somewhat retrospectively applied) twist to the tale in that by the end of his career, Campbell seemed to regard himself as one of the very first *antipositivist* social psychologists in the world (see [3], p. 504)!

Campbell enrolled at the University of California at Berkeley in the autumn of 1937, where he obtained his AB in 1939 (majoring in psychology). In the same year, he became a graduate student at Berkeley on a doctoral topic supervised by Harold Jones of the Institute of Child Welfare. This was, however, interrupted by two events: first, from 1940 to 1941, he took advantage of a travelling Fellowship to work at Harvard under Henry Murray (where he heard the social psychologist Gordon Allport lecture), and second by America's entry into World War II in 1941. Although his war service somewhat delayed his PhD work, the doctorate was awarded to him in 1947 for his research into the generality of social attitudes amongst five ethnic groups. Characteristically, Campbell's own account spends more time worrying about the methodology of the research than its content ([3],

p. 6). His academic rise was swift, from two stretches as assistant professor, first at Ohio State University and then at the University of Chicago (1947 to 1953), finally to an associate professorship at Northwestern University from 1953 until his retirement as emeritus professor in 1979. He achieved several major honors during his life: he was, for instance, awarded the American Psychological Association's Kurt Lewin Prize in 1974 and became the APA's President the following year. The National Academy of Sciences also honoured him with a Distinguished Scientific Contribution Award in 1970.

Although Donald Campbell is primarily judged by psychologists to be a methodologist, particular instances being his highly influential work on **multitrait-multimethod** and **quasi-experiments** [1], he is better understood as a theoretician of the social sciences who, because of his early and deep commitment to empirical realism and positivism, viewed improvements in *method* as the key to reliable truth. However, one could also characterize his work over the long term as attempts to fend off (or at least ameliorate) the more extreme aspects of a range of what he otherwise considered to be attractive philosophies and methodologies of science. Thus, *single variable operationism* was replaced by *multiple variable operationism* in his multitrait-multimethod work, without, however, dropping the essential commitment to *operationism*. Quasi-experimentation (see **Quasi-experimental Designs**) similarly was an explicit attempt to generalize standard Fisherian design and analysis (with its intellectual and quantitative rigor) from the tightly controlled psychological laboratory to the anarchic society outside on the street [2].

Canonical Correlation Analysis

Canonical correlation analysis (CCA) is a statistical method employed to investigate relationships among two or more variable sets, each consisting of at least two variables [7, 9, 10]. If a variable set consists of fewer than two variables, then canonical analysis is typically called something else, such as a *t* Test or a regression analysis (*see Multiple Linear Regression*). In theory, the canonical logic can be generalized to more than two variable sets [4], but in practice most researchers use CCA only with two variable sets, partly because commonly available software only accommodates this case.

Researchers use CCA and other multivariate methods (*see Multivariate Analysis: Overview*), instead of univariate methods (e.g., regression), for two reasons. First, CCA avoids the inflation of experiment-wise Type I error rates that typically results when multiple univariate analyses are conducted (*see Multiple Testing*). Second, by simultaneously considering all the variables in a single analysis, CCA honors the ecological reality that in nature all the variables can interact with each other. In other words, the same data when analyzed with multiple univariate methods may yield (a) statistically nonsignificant results and (b) zero effect sizes, but when analyzed with CCA may yield (a) statistically significant results and (b) huge effect sizes. And we tend to believe the multivariate results in such cases, because we tend to believe that in reality all the variables do interact with each other, and that only an analysis that honors this possibility generalizes well to reality.

In addition to being important from an applied research point of view, CCA also is important heuristically because it is a very general case of the **general linear model** [5]. The general linear model is the recognition that *all* analyses are correlational and yield r^2 -type effect sizes (e.g., percentage variance explained R^2 , Cohen's η^2), and all yield weights that are applied to the measured variables to produce estimates of the *latent* or *composite scores* (e.g., regression $\hat{Y}$ scores) that are actually the focus of the analysis. In other words, one can conduct a *t* Test using a CCA program, but not vice versa; an **analysis of variance** (ANOVA) using a CCA program,

but not vice versa; a **descriptive discriminant analysis** with a CCA program, but not vice versa; and so forth.

The first step in a CCA, performed automatically by software, is the computation of the bivariate product-moment **correlation matrix** involving all the variables [7]. Then the correlation matrix is partitioned into quadrants, honoring variable membership in the two variable sets. These quadrants are then multiplied times each other using matrix algebra. The resulting quadruple-product matrix is then subjected to a **principal component analysis** to yield the primary CCA results.

Given the computational starting point for CCA, most researchers use CCA when all the variables are intervally scaled. However, some researchers use CCA with dichotomous data or with a mixture of intervally scaled and dichotomous data (*see Measurement: Overview*). The primary difficulty with such analyses is that CCA assumes the data are multivariate normal (*see Catalogue of Probability Density Functions*), and data cannot be perfectly multivariate normal if some or all of the variables are dichotomous.

The fact that CCA invokes a principal component analysis [11] suggests the possibility of using **factor analysis** rather than CCA. Indeed, if in the researcher's judgment the variables do not constitute meaningful sets (e.g., variables measured at two different points in time, academic outcome variables versus personality variables), then factor analysis would be the appropriate way to explore relationships among the variables existing as a single set. But if sets are present, only CCA (and not factor analysis) honors the existence of the variable sets as part of the analysis.

CCA yields *canonical functions* consisting of both standardized weights, similar to regression beta weights (*see Standardized Regression Coefficients*), that can be used to derive *canonical scores*, and *structure coefficients*, r_s , which are bivariate correlations of the measured variables with the canonical composite scores [7, 10]. The number of functions equals the number of variables in the smaller of the two variable sets and each function represents two weighted sums, one for each set of variables. Each function also yields a *canonical correlation coefficient* (R_C) ranging from 0.0 to 1.0, and a squared canonical correlation coefficient (R_C^2). One criterion that is optimized by CCA is that on a given

2 Canonical Correlation Analysis

function the weights, called *standardized canonical function coefficients*, optimize R_C^2 just as regression beta weights optimize R^2 .

The canonical functions are uncorrelated or orthogonal. In fact, the functions are ‘bi-orthogonal’. For example, if there are two functions in a given analysis, the canonical scores on Function I for the criterion variable set are (a) perfectly uncorrelated with the canonical scores on Function II for the criterion variable set and (b) perfectly uncorrelated with the canonical scores on Function II for the predictor variable set. Additionally, the canonical scores on Function I for the predictor variable set are (a) perfectly uncorrelated with the canonical scores on Function II for the predictor variable set and (b) perfectly uncorrelated with the canonical scores on Function II for the criterion variable set. Each function theoretically can yield squared canonical correlations that are 1.0. In this case, because the functions are perfectly uncorrelated, each function perfectly explains relationships of the variables in the two variable sets, but does so in a unique way.

As is the case throughout the general linear model, interpretation of CCA addresses two questions [10]:

1. ‘Do I have anything?’, and, if so
2. ‘Where does it (my effect size) come from?’.

The first question is addressed by consulting some combination of evidence for (a) statistical significance, (b) effect sizes (e.g., R_C^2 or adjusted R_C^2 [8]), and (c) result replicability (see **Cross-validation; Bootstrap Inference**). It is important to remember

that in multivariate statistics one can only test the statistical significance of a function as a single function (i.e., the last function), unless one uses a **structural equation modeling** approach to the analysis [2].

If the researcher decides that the results reflect nothing, the second question is rendered irrelevant, because the sensible researcher will not ask, ‘From where does my nothing originate?’ If the researcher decides that the results reflect more than nothing, then both the standardized function coefficients and the structure coefficients must be consulted, as is the case throughout the general linear model [1, 3]. Only variables that have weight and structure coefficients of zero on all functions contribute nothing to the analysis.

A heuristic example may be useful in illustrating the application. The example is modeled on real results presented by Pitts and Thompson [6]. The heuristic presumes that participants obtain scores on two reading tests: one measuring reading comprehension when readers have background knowledge related to the reading topic (SPSS variable name *read_yes*) and one when they do not (*read_no*). These two reading abilities are predicted by scores on vocabulary (*vocabulr*), spelling (*spelling*), and self-concept (*self_con*) tests. The Table 1 data cannot be analyzed in SPSS by point-and-click, but canonical results can be obtained by executing the syntax commands:

```
MANOVA read_yes read_no WITH
  vocabulr spelling self_con/
  PRINT=SIGNIF(MULTIV EIGEN
  DIMENR) /
```

Table 1 Heuristic data

Person	SPSS Variable Names						
	<i>read_yes</i>	<i>read_no</i>	<i>vocabulr</i>	<i>spelling</i>	<i>self_con</i>	CRIT1	PRED1
Herbert	61 (−1.49)	58 (1.41)	81 (−1.70)	80 (−0.72)	68 (−0.67)	−1.55	−1.59

Gertrude	73 (0.50)	49 (−0.67)	99 (1.16)	87 (0.48)	85 (1.32)	0.53	0.63
Kelly	75 (0.83)	52 (0.02)	98 (1.00)	86 (0.31)	75 (0.15)	0.82	1.04
Murray	77 (1.16)	55 (0.72)	95 (0.52)	82 (−0.38)	61 (−1.49)	1.12	1.29
Wendy	79 (1.49)	58 (1.41)	99 (1.16)	94 (1.67)	80 (0.74)	1.42	1.10

Note: The z -score equivalents of the five measured variables are presented in parentheses. The scores on the canonical composite variables (e.g., CRIT1 and PRED1) are also in z -score form.

Table 2 Canonical results

SPSS Variable	Function I			Function II		
	Function	r_s	Squared	Function	r_s	Squared
read_yes	1.002	0.999	99.80%	-0.018	0.046	0.21%
read_no	-0.046	0.018	0.03%	1.001	1.000	100.00%
Adequacy			49.92%			50.11%
Redundancy			48.52%			36.98%
R_c^2			97.20%			73.80%
Redundancy			30.78%			8.28%
Adequacy			31.67%			11.22%
vocabulr	1.081	0.922	85.01%	-0.467	-0.077	0.59%
spelling	0.142	0.307	9.42%	1.671	0.575	33.06%
self_con	-0.520	0.076	0.58%	-1.093	-0.003	0.00%

Note: The canonical adequacy coefficient equals the average squared structure coefficient for the variables on a given function [7, 10]. The canonical redundancy coefficient equals the canonical adequacy coefficient times the R_c^2 [7, 9].

DISCRIM=STAN CORR
ALPHA(.999) / .

Table 2 presents the canonical results organized in the format recommended elsewhere [9, 10]. The standardized function coefficients can be used to compute the composite or latent scores on the canonical functions. For example, on the first canonical function, Wendy's criterion composite score on Function I would be her z -scores times the Function I criterion standardized canonical function coefficients ($[1.49 \times 1.002] + [1.41 \times -0.046] = 1.42$). Wendy's predictor composite score on Function I would be her z -scores times the Function I predictor standardized canonical function coefficients ($[1.16 \times 1.081] + [1.67 \times 0.142] + [0.74 \times -0.520] = 1.10$). It is actually the composite scores that are the focus of the CCA, and *not* the measured variables (e.g., read_yes, vocabulr). The measured variables are useful primarily to obtain the estimates of the construct scores. For example, the Pearson r^2 between the Function I composite scores in Table 1 is 0.972. This equals the R_c^2 on Function I, as reported in Table 2.

The heuristic data are useful in emphasizing several points:

1. The standardized canonical function coefficients, like regression beta weights [1], factor pattern coefficients [11], and so forth, are not generally correlation coefficients (e.g., 1.671, -1.093, and 1.081), and therefore cannot be interpreted as measuring the strength of relationship.
2. Because the canonical functions are orthogonal, all functions theoretically could have squared canonical correlation coefficients (here 0.972 and 0.738) of 1.0, and do not sum to 1.0 across functions.
3. Even variables essentially uncorrelated with the measured variables in another variable set (e.g., self_con) can be useful in improving the effect size, as reflected by such variables having near-zero structure coefficients (e.g., 0.076 and -0.003) but large function coefficients (e.g., -0.520 and -1.093).

The latter dynamic of 'suppression' can occur in canonical analysis, just as it can occur throughout the general linear model [1], in analyses such as the regression analysis or descriptive discriminant analysis.

Carroll–Arabie Taxonomy

Text

A large number of computerized scaling techniques were developed in the wake of the pioneering work of Shepard, Kruskal, and Guttman [4–6, 8, 9] (*see Multidimensional Scaling*). There have been various attempts to bring some order into this bewildering variety of techniques. Books such as [7] or review articles such as [3] are organized with a clear taxonomy in mind, but the most well-known and comprehensive organization of scaling methods is due to Carroll and Arabie [1].

Before we discuss the taxonomy, we have to emphasize two important points. First, the proposed organization of scaling methods is clearly inspired by earlier work of Coombs [2] and Shepard [10]. The exquisite theoretical work of Coombs was written before the computer revolution, and the scaling methods he proposed were antiquated before they were ever seriously used. This had the unfortunate consequence that the theoretical work was also largely ignored. The same thing is more or less true of the work of Shepard, who actually did propose computerized algorithms, but never got them beyond the stage of research software. Again, this implied that his seminal contributions to multidimensional scaling have been undervalued. Both Coombs and Shepard had some followers, but they did not have an army of consumers who used their name and referred to their papers. The second important aspect of the Carroll–Shepard taxonomy is that it was written around 1980. In the subsequent 25 years, hundreds of additional metric and nonmetric scaling methods have been developed, and some of them fall outside the boundaries of the taxonomy. It is also probably true that the messianistic zeal with which the nonmetric methods were presented around 1970 has subsided. They are now much more widely employed, in many different disciplines, but shortcomings have become apparent and the magic has largely dissipated.

The actual taxonomy is given in Table 1. We give a brief explanation of the concepts that are not self-evident. The ‘number of ways’ refers to the dimensionality of the data array and the ‘number of modes’ to the number of sets of objects that must be represented. Thus a symmetric matrix of proximities has two ways but one mode. ‘Scale type’

Table 1 Carroll–Arabie taxonomy of scaling methods

-

refers to the usual nominal, ordinal, and numerical distinction. ‘Conditionality’ defines which elements of the data array can be sensibly compared. Thus a matrix with preference rank order in each row is row-conditional. Matrices with similarity rankings between, say, colors, by a number of different subjects, gives three-way, two-mode, ordinal, matrix conditional data. ‘Completeness’ refers to missing data, sometimes in the more theoretical sense in which we say that unfolding data are incomplete, because they only define an off-diagonal submatrix of the complete similarity matrix (*see Multidimensional Unfolding*).

The taxonomy of models is somewhat dated. It is clear the authors set out to classify the existing scaling techniques, more specifically the computerized ones they and their coworkers had developed (which happened to be a pretty complete coverage of the field at the time). We can clearly distinguish the nonmetric scaling methods, the influence of using Minkovski power metrics, the work on cluster analysis (*see Cluster Analysis: Overview*) and additive partitioning, and the work on internal and external analysis of preferences. Some clarifications are perhaps needed. ‘Number of spaces’ refers to either a joint or a separate representation of the two modes of a matrix (or the multiple modes of an array). Such considerations are especially important in off-diagonal methods such as unfolding or correspondence analysis. ‘External’ analysis implies that coordinates in one of the spaces in which we are representing our data are fixed

2 Carroll–Arabie Taxonomy

(usually found by some previous analysis, or defined by theoretical considerations). We only fit the coordinates of the points in other spaces; for instance, we have a two-dimensional space of objects and we fit individual preferences as either points or lines in that space.

In summary, we can say that the Carroll–Arabie taxonomy can be used to describe and classify a large number of scaling methods, especially scaling methods developed at Bell Telephone Laboratories and its immediate vicinity between 1960 and 1980. Since 1980, the field of scaling has moved away to some extent from the geometrical methods and the heavy emphasis on solving very complicated optimization problems. Item response theory and choice modeling have become more prominent, and they are somewhat at the boundaries of the taxonomy. New types of discrete representations have been discovered. The fact that the taxonomy is still very useful and comprehensive attests to the importance of the frameworks developed during 1960–1980, and to some extent also to the unfortunate fact that there no longer is a center in psychometrics and scaling with the power and creativity of Bell Labs in that area.

Carryover and Sequence Effects

‘Carryover’ and ‘sequence’ effects are nuisance parameters (see **Nuisance Variables**) that may arise when repeated measurements are collected on subjects over time. In experimental studies, carryover is a lingering effect of a treatment administered in one period into the subsequent period. Carryover effects are differences in carryover between two treatments, while sequence effects are differences in overall responses between subjects receiving treatments in different orders [6, 11, 14, 16]. Carryover and sequence effects may occur in **observational studies**. For example, the ordering of items in a questionnaire might affect overall response, while the response to an individual item may be influenced by the previous item(s) [15]. Our review focuses on experimental studies, although the principles could extend to observational studies (for a general discussion of repeated measures studies, see [5] or [16]).

To illustrate, first imagine a study where two levels of a single factor (E : Experimental and S : Standard) are of interest and where n subjects, acting as blocks, are each available for two measurement periods. For example, E might be a behavioral intervention to improve short-term memory in patients with Alzheimer’s disease, whereas S refers to standard care. If effects due to sequence, carryover, and period (temporal changes that affect all patients) are not of concern, then each patient could receive E followed by S . With respect to carryover, we specifically assume that the experimental intervention administered in the first period does not influence short-term memory in the second period. In the analysis of this design, carryover from E into S cannot be estimated separately from the treatment effect, that is, carryover is confounded with the treatment effect.

Alternatively, we might randomly assign patients to E followed by S , in sequence 1 (ES), or S followed by E , in sequence 2 (SE). This ‘crossover’ study is a type of split-plot **factorial design** [6, 11]. In split-plot factorials, we have two factors of interest. In the **repeated measures** setting, we randomize n_i ($i = 1, \dots, s$) subjects to receive one of the s levels of the *between-subject* factor; we apply the p levels of the *within-subject* factor to each subject sequentially (Table 1). Thus, each subject

Table 1 Layout for split-plot factorial design in a repeated measures setting

Between-subject factor	Subject	Within-subject factor			
1	1	1	...	p	
⋮	⋮	⋮		⋮	
1	n_1	1	...	p	
⋮	⋮	⋮		⋮	
s	1	1	...	p	
⋮	⋮	⋮		⋮	
s	n_s	1	...	p	

receives only one of the levels of the between-subject factors but all levels of the within-subject factor. In **crossover designs**, sequence effects (ES versus SE) are individual levels of the between-subject factor while the individual treatments (E and S) can be thought of as levels of the within-subject factor (Table 2). In an alternative split-plot design ($EE:SS$), we might randomly assign patients to receive either E or S and then make two weekly measurements. Here, E and S (or EE and SS) are levels of the between-subject factor, while time is the within-subject factor. As we will see, the estimate of the treatment effect in the crossover design is based on within-subject differences. Typically, this design is more efficient and requires far fewer subjects than the $EE:SS$ design where the estimate of the treatment effect is based on a between-subject comparison [13].

As an example, consider a **clinical trial** comparing experimental therapy (nasal corticosteroids, Treatment E) and placebo (Treatment S) on self-reported daytime sleepiness in patients with allergic rhinitis [4]. Table 3 shows the data for nine patients on the $ES:SE$ portion of the crossover study for whom data were available for both periods. The datum for one patient from the ES sequence was missing for the second period. Patients who were randomly assigned to either S or E self-administered their treatments

Table 2 Layout for $ES:SE$ and $EE:SS$ designs

Design	Sequence	Period	
		1	2
$ES:SE$	ES	E	S
$ES:SE$	SE	S	E
$EE:SS$	EE	E	E
$EE:SS$	SS	S	S

2 Carryover and Sequence Effects

Table 3 Mean weekly IDS score by period and mean difference between periods for individual patients on the TP and PT sequences [12]. Reprinted with permission from the *Journal of the American Statistical Association*. Copyright 2002 by the American Statistical Association

Sequence 1 (ES)					
Patient	1	2	3	4	5
Period 1	2.00	1.83	0	0.89	3.00
Period 2	1.29	0	0	NA	3.00
Difference	0.36	0.92	0	NA	0

Sequence 2 (SE)					
Patient	1	2	3	4	5
Period 1	4.00	0	0	1.14	0
Period 2	4.00	0.86	0	2.14	2.29
Difference	0	-0.43	0	-0.50	-1.15

over an eight-week period. They then crossed over to the other treatment (without washout) for a second eight-week period of treatment. Each patient rated their improvement in daytime sleepiness (IDS) on a scale of 0 (worst) to 4 (best) on a daily basis. We analyzed average IDS over the final week in each eight-week treatment period and assumed that weekly averaging of the ordinal IDS scores yielded data on a continuous scale.

Statistical Model. Let Y_{ijkl} be the outcome for the j th subject ($j = 1, \dots, n_i$) from the i th sequence ($i = 1, 2$) on the k th treatment ($k = S, E$) in the l th period ($l = 1, 2$). Then

$$Y_{ijkl} = \mu_k + \pi_l + \lambda_{k'_{l-1}} + \delta_i + \varepsilon_{ijkl}, \quad (1)$$

for μ_k , the mean response for the k th treatment; π_l , the mean added effect for the l th period; $\lambda_{k'_{l-1}}$, the mean added effect due to carryover of the k' th treatment administered in the $(l-1)$ th period into the subsequent period ($\lambda_{k'_0} = 0$); and δ_i , the mean added effect for the i th sequence. The ε_{ijkl} is a random error term. Subjects are independent with $E(\varepsilon_{ijkl}) = 0$, $\text{Var}(\varepsilon_{ijkl}) = \sigma^2$, and $\text{Cov}(\varepsilon_{ijkl}, \varepsilon_{ijk'l'}) = \rho\sigma^2$ for $k \neq k'$ and $l \neq l'$, where ρ is the correlation coefficient.

Estimation and Testing. Table 4 gives the expectation of the outcome for each sequence/period combination as well as for Y_{ij}^* , the mean difference of periods for each subject that is,

$$Y_{ij}^* = \frac{1}{2}(Y_{ijk1} - Y_{ijk2}) \quad (2)$$

and $\mu_D = \mu_E - \mu_S$. The variance of each Y_{ij}^* is

$$\text{Var}(Y_{ij}^*) = \frac{1}{2}\sigma^2(1 - \rho) \quad (3)$$

We combine means of the Y_{ij}^* 's for each sequence, to yield estimates of the treatment effect, that is,

$$\hat{\mu}_D = (\bar{Y}_1^* - \bar{Y}_2^*) \quad (4)$$

for $\bar{Y}_i^* = 1/n_i \sum_{j=1}^{n_i} Y_{ij}^*$. In turn, $\hat{\mu}_D$ has expectation

$$E(\hat{\mu}_D) = \mu_D - \frac{1}{2}\lambda_D \quad (5)$$

for $\lambda_D = \lambda_{E1} - \lambda_{S1}$. The expectation of $\hat{\mu}_D$ is unaffected by period or sequence effects. However in the presence of carryover effects ($\lambda_D \neq 0$), $\hat{\mu}_D$ is biased for μ_D . To put these results in the context of the IDS example, suppose that patients receiving *SE* were, on average, sleepier than patients on *ES*, yielding a sequence effect ($\delta_1 < \delta_2$). In addition, suppose that daytime sleepiness was recorded in the morning for Period 1 and in the afternoon for Period 2, causing a period effect ($\pi_1 > \pi_2$). Under our model, neither nuisance parameter biases $\hat{\mu}_D$. The within-subject comparison eliminates sequence effects; the between-subject comparison eliminates period effects. On the other hand, suppose that daytime sleepiness improved on *E* compared to *S*, that measurements were collected in sequential weeks, rather than over an eight-week period, and that some aspect of the effect of *E* lingered into the week subsequent to its administration. Then, in Period 2 of Sequence 1, we would tend to see IDS scores higher than expected for subjects receiving *S* alone. This carryover effect biases $\hat{\mu}_D$; when λ_D and $\hat{\mu}_D$ have the same sign, $\hat{\mu}_D$ underestimates the true treatment effect, μ_D [13].

Table 4 Expectations for the *ES:SE* design by period

Sequence	Period 1	Period 2	Difference (Y_{ij}^*)
1 (ES)	$\mu_E + \pi_1 + \delta_1$	$\mu_S + \pi_2 + \lambda_{E1} + \delta_1$	$\frac{1}{2}\mu_D + \frac{1}{2}(\pi_1 - \pi_2) - \frac{1}{2}\lambda_{E1}$
2 (SE)	$\mu_S + \pi_1 + \delta_2$	$\mu_E + \pi_2 + \lambda_{S1} + \delta_2$	$-\frac{1}{2}\mu_D + \frac{1}{2}(\pi_1 - \pi_2) - \frac{1}{2}\lambda_{S1}$

In most crossover studies, interest lies in estimating μ_D and testing for nonzero treatment effects. If the sample size is large, or the data are normally distributed, a hypothesis test of

$$H_0: \mu_D - \frac{1}{2}\lambda_D = 0 \quad \text{versus} \quad H_1: \mu_D - \frac{1}{2}\lambda_D \neq 0 \quad (6)$$

can be constructed using

$$t^* = \frac{\hat{\mu}_D}{\sqrt{\frac{s^2}{4} \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}}. \quad (7)$$

Here s^2 is the pooled sample variance of the Y_{ij}^* 's ($s^2 = (n_1 - 1)s_1^2 + (n_2 - 1)s_2^2 / (n_1 + n_2 - 2)$), where s_i^2 is the sample variance of the Y_{ij}^* 's for the i th sequence. Under H_0 , t^* has a t distribution with $n_1 + n_2 - 2$ degrees of freedom. A $100(1 - \alpha)\%$ **confidence interval** (CI) for $\mu_D - 1/2\lambda_D$ is simply

$$\hat{\mu}_D \pm t_{n_1+n_2-2, 1-\alpha/2} \sqrt{\frac{s^2}{4} \left(\frac{1}{n_1} + \frac{1}{n_2} \right)},$$

where α is the level of the CI and $t_{n_1+n_2-2, 1-\alpha/2}$ is the $1 - \alpha/2$ th quantile of the $t_{n_1+n_2-2}$ distribution. We show numerical results for the example in Table 5.

For a Type I error rate of 0.05, these results suggest that corticosteroids improve daytime sleepiness, with the interval (0.01, 1.45 units) containing the mean improvement with high confidence.

It is straightforward to see that for the $EE:SS$ design, the treatment effect is estimated from the difference of the mean of the repeated measurements for each subject, and that the remainder of the procedures described for the crossover can be applied. Using the model in Equation (1), the expectation of this estimate is $\mu_D + 1/2(\delta_1 - \delta_2) + 1/2(\lambda_D)$ that is biased by both sequence and carryover effects. If the study is randomized, then δ_1 and δ_2 should be equal. In addition, carryover here represents the effect of repeated administrations of the same treatment, as opposed to the crossover's lingering effect of one treatment into another, an effect that may be more

interpretable in the context of the study. However, in contrast to the crossover study, the mean of the repeated measurements for each subject has variance $\frac{1}{2}\sigma^2(1 + \rho)$, and this yields a larger variance of the estimated treatment effect. As an example, the IDS study included both EE and SS sequences, each with five subjects (data not shown). Here the estimated treatment effect of 0.85 was slightly larger than the estimate using the crossover portion of the study. However, the 95% confidence interval of $(-0.70, 2.40)$ was substantially wider, while the P value for the hypothesis test was 0.24, suggesting substantial loss in precision compared to the $ES:SE$ portion of the study.

Further Considerations. Potential biases generated by carryover or sequence effects can be addressed in either the design or the analysis of the study. As we showed, two different split-plot designs yield different biases, but also different efficiencies. In addition to split-plot factorial designs, designs where carryover and sequence effects should be considered include **randomized block** and randomized block factorial designs [11]. We focused on simple two-treatment, two-period designs. However, additional measurement and/or washout periods may reduce carryover effects and/or improve the efficiency of these designs [1, 3, 13, 16]. We note that baseline measurements can substantially improve the efficiency of the $EE:SS$ design [12]. We can also add additional levels of either the between or the within-subject factor [11]. Each change in design requires modeling assumptions, and particularly assumptions about carryover, that should be evaluated carefully in the context of the study. Moreover, the reader should be aware of arguments against using more elaborate crossover designs. Senn [14, Chapter 10] argues that assumptions used to develop these approaches do not provide a useful approximation to reality, and that the approach may ultimately yield biased results.

For the $ES:SE$ design, we note that λ_D can be estimated from the difference of the sums of the two periods for each individual. Because this estimate is based on a between-subject comparison, it is

Table 5 Expectations for $ES:SE$ daytime sleepiness example by period

Variable	$\hat{\mu}_D$	s_1	s_2	s	t^*	P value ^a	95% CI
Estimate	0.73	0.864	0.941	0.909	2.39	0.048	(0.01, 1.45)

^aTwo-sided test.

4 Carryover and Sequence Effects

less efficient than the estimate of the treatment effect, and the **power** to detect carryover is typically very small [2]. In contrast, λ_D , while typically not of great interest in the $EE:SS$ design, is estimated efficiently from a within-subject comparison. Grizzle's popular two-stage method used a test for the presence of a carryover effect to determine whether to use both or only the first period of data to estimate μ_D in the crossover design [8, 9]. This analysis is fundamentally flawed, with Type I error rates in excess of the nominal Type I error rates in the absence of carryover [7].

Lastly, **analysis of variance** or mixed-effects models (see **Generalized Linear Mixed Models; Linear Multilevel Models**) extend the analyses we have described here, and provide a unified framework for analyzing the repeated measures studies [5, 10, 11, 16].

Case Studies

A case study is an intensive and rigorous empirical investigation of a contemporary phenomenon within its real-life context [9, 16, 17, 20]. In behavioral science, the phenomenon usually refers to an individual, but it can also refer to a group of individuals (e.g., a family or a neighborhood), to an organization (e.g., a company or a school), or to a set of procedures (e.g., a public program or a community intervention). The fact that a case study deals with a contemporary phenomenon makes the distinction with a historical study. The contextual nature of case studies implies that there are many more variables of interest than data points, and this represents the major methodological challenge when trying to draw valid conclusions from case studies. As a further complication, case studies are used most often when the researcher has little or no control over the phenomenon [2, 20].

The Case for Case Study Research

Some researchers and methodologists have discounted case studies as a potential source of valid conclusions because they identified the case study with the preexperimental ‘one-shot case study’, using Campbell and Stanley’s terminology (see **Quasi-experimental Designs**) [4]. However, this dismissal is based on a misunderstanding: ‘one-shot case study’ has been a misnomer for a design that only includes one group and one posttest; a design that has little bearing on case studies as such. In a revision of their design classification and terminology, Cook and Campbell [6] emphasized: ‘Certainly the case study as normally practiced should not be demeaned by identification with the one-group posttest-only design’ (p. 96). In his foreword to Yin’s handbook on case study research, Campbell [3] confirms:

‘[This book on case study research] It epitomizes a research method for attempting valid inferences from events outside the laboratory while at the same time retaining the goals of knowledge shared with laboratory science’ (p. ix).

According to Yin [19, 20], one of the most important strategies for drawing valid conclusions from a case study is the reliance on theory, hypotheses, and concepts to guide design and data collection. Reliance

on theory enables the researcher to place the case study in an appropriate research literature, to help define the boundaries of the case and the unit of analysis, and to suggest the relevant variables and data to be collected. To counter the underidentification of the potential theoretical propositions (cf. the above mentioned ‘many more variables of interest than data points’), case study researchers have to bring into action multiple sources of evidence, with data needing to converge in a triangulating fashion. A prototypical example is Campbell’s pattern-matching strategy [2] that has been used successfully to show that the decreasing level of traffic fatalities in Connecticut was not related to the lowering of the speed limit, and which involved linking several pieces of information from the same case to some theoretical proposition. Other strategies to enable valid conclusions from case studies include collecting systematic and objective data, using continuous assessment or observations during an extended period of time, looking at multiple cases to test tentative hypotheses or to arrive at more general statements, and applying formal data-analytic techniques [9, 10].

What is the Case?

A case may be selected or studied for several reasons. It may be that it is a *unique case*, as, for example, with specific injuries or rare disorders. But it may also be that it represents a *critical case* in testing a well-formulated theory or a *revelatory case* when a researcher has the opportunity to observe and analyze a phenomenon previously inaccessible to scientists [20]. Famous case studies were crucial in the development of several psychological phenomena (e.g., Little Hans, Anna O., Little Albert) [9] and series of cases have exerted a tremendous impact on subsequent research and practice (e.g., in sexology [11] and behavior modification [18]). In more recent years, case study research has been adopted successfully and enthusiastically in cognitive neuropsychology, in which the intensive study of individual brain-damaged patients, their impaired performance and double dissociations have provided valid information about, and invaluable insights into, the structure of cognition [5, 14]. For example, Rapp and Caramazza [13] have described an individual who exhibited greater difficulties in speaking nouns than verbs and greater difficulties in writing verbs

than nouns, and this double dissociation of grammatical category by modality within a single individual has been presented as a serious challenge to current neurolinguistic theories.

Cases in All Shapes and Sizes

When we look at the diversity of the case study literature, we will notice that there are various types of case studies, and that there are several possible dimensions to express this multitude. A first distinction might refer to the kind of paradigm the researcher is working in. On the one hand, there is the more quantitative and analytical perspective of, for example, Yin [19, 20]. On the other hand, there is also the more qualitative and ethnographic approach of, for example, Stake [15, 16]. It is important to give both *quantitative* and *qualitative case studies* a place in behavioral science methodology. As Campbell [3] remarked:

It is tragic that major movements in the social sciences are using the term *hermeneutics* to connote *giving up* on the goal of validity and abandoning disputation as to who has got it right. Thus, in addition to the quantitative and quasi-experimental case study approach that Yin teaches, our social science methodological armamentarium also needs a humanistic validity-seeking case study methodology that, while making no use of quantification or tests of significance, would still work on the same questions and share the same goals of knowledge. (italics in original, p. ix–x)

A second distinction might refer to the kind of research problems and questions that are addressed in the case study. In a *descriptive case study*, the focus is on portraying the phenomenon, providing a chronological narrative of events, citing numbers and facts, highlighting specific or unusual events and characteristics, or using ‘thick description’ of lived experiences and situational complexity [7]. An *exploratory case study* may be used as a tryout or act as a pilot to generate hypotheses and propositions that are tested in larger scale surveys or experiments. An *explanatory case study* tackles ‘how’ and ‘why’ questions and can be used in its own right to test causal hypotheses and theories [20].

Yin [20] uses a third distinction referring to the study design, which is based on the number of cases and the number of units of analysis within each case. In *single-case holistic designs*, there is only one case and a single unit of analysis. In *single-case*

embedded designs, there is also only one case, but, in addition, there are multiple subunits of analysis, creating opportunities for more extensive analysis (e.g., a case study of school climate may involve teachers and pupils as subunits of study). *Multiple-case holistic designs* and *multiple-case embedded designs* are the corresponding designs when the same study contains more than one case (e.g., a case study of school climate that uses a multiple-case design implies involving several schools).

Just in Case

As Yin [20] observed: ‘Case study research is remarkably hard, even though case studies have traditionally been considered to be “soft” research. Paradoxically, the “softer” a research strategy, the harder it is to do’ (p. 16). Here are some common pitfalls in case study research (based on the recommendations in [12]):

- *Bad journalism*. Selecting a case out of several available cases because it fits the researcher’s theory or distorting the complete picture by picking out the most sensational features of the case.
- *Anecdotal style*. Reporting an endless series of low-level banal and tedious nonevents that take over from in-depth rigorous analysis.
- *Pomposity*. Deriving or generating profound theories from low-level data, or by wrapping up accounts in high-sounding verbiage.
- *Blandness*. Unquestioningly accepting the respondents’ views, or only including safe uncontroversial issues in the case study, avoiding areas on which people might disagree.

Cases in Point

Instructive applications of case study research and additional references can be found in [1, 8, 15, 19]. Many interesting case studies from clinical psychology and family therapy can be found in ‘*Clinical Case Studies*’, a journal devoted entirely to case studies.

Case–Cohort Studies

The case-cohort design is a method of sampling from an assembled epidemiologic cohort study or clinical trial in which a random sample of the cohort, called the *subcohort*, is used as a comparison group for all cases that occur in the cohort [10]. This design is generally used when such a cohort can be followed for disease outcomes but it is too expensive to collect and process covariate information on all study subjects. Though it may be used in other settings, it is especially advantageous for studies in which covariate information collected at entry to the study is ‘banked’ for the entire cohort but is expensive to retrieve or process and multiple disease stages or outcomes are of interest. In such circumstances, the work of covariate processing for subcohort members can proceed at the beginning of the study. As time passes and cases of disease occur, information for these cases can be processed in batches. Since the subcohort data is prepared early on and is not dependent on the occurrence of cases, statistical analyses can proceed at regular intervals after the processing of the cases. Further, staffing needs are quite predictable. The design was motivated by the case-base sampling method for simple binary outcome data [6, 8]. Parameters of interest in case-cohort studies are usual rate ratios in a Cox proportional hazards model (see **Survival Analysis**) [4].

Design

The basic components of a case-cohort study are the *subcohort*, a sample of subjects in the cohort, and *non-subcohort cases*, subjects that have had an event and are not included in the subcohort. The subcohort provides information on the person-time experience of a random sample of subjects from the cohort or random samples from within strata of a confounding factor. In the latter situation, differing sampling fractions could be used to better align the person-time distribution of the subcohort with that of the cases. Methods for sampling the subcohort include sampling a fixed number without replacement [10] and sampling based on independent Bernoulli ‘coin flips’ [14]. The latter may be advantageous when subjects are entered into the study prospectively;

the subcohort may then be formed concurrently rather than waiting until accrual into the cohort has ended [12, 14]. Simple case-cohort studies are the same as case-base studies for simple binary outcome data. But, in general, portions of a subject’s time on study might be sampled. For example, the subcohort might be ‘refreshed’ by sampling from those remaining on study after a period of time [10, 15]. These subjects would contribute person-time only from that time forward. While the subcohort may be selected on the basis of covariates [3, 10], a key feature of the case-cohort design is that the subcohort is chosen without regard to failure status; methods that rely on failure status in the sampling of the comparison group are **case-control studies**.

Examples

Study of lung cancer mortality in aluminum production workers in Quebec, Canada

Armstrong et al. describe the results of a case-cohort study selected from among 16 297 men who had worked at least one year in manual jobs at a large aluminum production plant between 1950 and 1988 [1]. This study greatly expands on an earlier cohort mortality study of the plant that found a suggestion of increased rates of lung cancer in jobs with high exposures to coal tar pitch [5]. Through a variety of methods, 338 lung cancer deaths were identified. To avoid the expense associated with tracing subjects and abstraction of work records for the entire cohort, a case-cohort study was undertaken. To improve study efficiency, a subcohort of 1138 subjects was randomly sampled from within year of birth strata with sampling fractions varying to yield a similar distribution to that of cases. This was accommodated in the analysis by stratification by these year of birth categories. The random sampling of subcohort members resulted in the inclusion of 205 cases in the subcohort. Work and smoking histories were abstracted for the subcohort and the additional 133 non-subcohort cases. Cumulative exposure to coal tar pitch volatiles were estimated by linking worker job histories to the measurements of chemical levels made in the plant using a ‘job-exposure matrix’. The analyses confirmed the lung cancer–coal pitch association observed in the earlier study and effectively ruled out confounding by smoking.

Genetic influences in childhood asthma development in the Children's Health Study in Los Angeles, California

The Children's Health Study at the University of Southern California has followed a cohort of school-aged children and recorded measures of respiratory health since 1993 [9]. Buccal cell samples have been collected and stored on a large proportion of cohort subjects and it was desired to retrospectively investigate genetic and environmental influences on incident asthma rates in this age group. Because the genotyping lab work is expensive, this study is to be done using a sample of the cohort. One complication of this study is that asthma was not a primary endpoint of the original study and incident asthma occurrence is available only as reported by the subject or the parents. It is believed that about 30% of the self-reported asthma cases will not be confirmed as 'physician diagnosed', the criterion for study cases. Because control selection is not tied to case determination, a case-cohort design allows selection of the comparison group prior to case confirmation. A subcohort will be randomly selected and all of these subjects interviewed and genotyped. Both subcohort and non-subcohort self-reported asthma subjects will be confirmed as to case status. Non-subcohort self-reported asthma subjects who are not confirmed are dropped from the study, while those in the subcohort are simply assigned their confirmed status.

Computer Software

Rate ratios from the Cox model can be computed using any Cox regression software. However, the variance is not properly estimated. A number of methods have been implemented in software packages. The 'Prentice' estimator [10] is a rather complicated expression and only one software package has implemented it (Epicure, Hirosoft International Corp., Seattle, WA, www.hirosoft.com). Simpler alternatives are the 'asymptotic' [11] and 'robust' variance estimators [7, 2]. Either may be computed by simple manipulation of δ and β diagnostic statistics, which are an output option in many software packages [13]. The asymptotic estimator requires the sampling fractions while the robust estimates these from the data.

Case–Control Studies

Case–Control Study

A case–control study is an observational study, meaning that there is no **randomization** used in the design. The studied subjects make their own choices regarding exposures or treatments, and the investigators observe both the group to which each individual belongs and the corresponding outcome. In contrast, a randomized trial is an experimental study, in which investigators control the group to which a patient belongs by randomly assigning each patient to a treatment group. There are several types of observational studies, such as the case–control study, the cohort study (*see Case–Cohort Studies*), and the cross-sectional study (*see Cross-sectional Design*) [1]. In case–control studies, investigators observe subjects with and without disease, and then look back to assess the antecedent risk factors. In cohort studies, investigators follow subjects with and without a risk factor or exposure, and follow them to determine if they develop the disease.

Cohort studies may not be suitable for studying associations between exposures and diseases that take a long time to develop, such as the association between smoking and lung cancer. Clearly, such a study, if conducted as a cohort study, would require a long time to follow up and a large sample size. If, however, the investigator decides to use a case–control study instead, then the required time between exposure and disease would have already elapsed, and so the time required would be considerably less. If D represents disease (for example, myocardial infarction), E represents exposure (e.g., oral contraception), $\bar{D}$ represents no myocardial infarction, and $\bar{E}$ represents no oral contraception, then for cohort studies the **relative risk (RR)** should be calculated as follows:

$$RR = \frac{P(D|E)}{P(D|\bar{E})}. \quad (1)$$

In a case–control study, the marginal totals for disease (i.e., the total number of subjects with disease, or cases, and the total number of subjects without disease, or controls) is fixed by design (the sampling scheme determines these totals). What is random is the exposure marginal totals (i.e., the total number of

exposed subjects and the total number of unexposed subjects), and the cell counts. It is more common to estimate the relative risk when the exposure margin is fixed by design and the distribution of cases and controls, both overall and within each exposure group, is random. That this is not the case introduces conceptual difficulties with directly estimating the relative risk in case–control studies. One solution is to estimate $P(D|E)$ indirectly, by first estimating $P(E|D)$ directly, and then applying Bayes’ theorem: (*see Bayesian Belief Networks*)

$$P(D|E) = \frac{P(E|D)P(D)}{P(E|D)P(D) + P(E|\bar{D})P(\bar{D})}. \quad (2)$$

The only unknown quantity in this expression is $P(D)$, which is the prevalence of the disease in the whole population. This quantity, $P(D)$, can be estimated from prior knowledge, or perhaps a range of values can be considered to reflect uncertainty. The **odds ratio (OR)** is computed as

$$OR = \frac{P(D|E)/P(\bar{D}|E)}{P(D|\bar{E})/P(\bar{D}|\bar{E})} = \frac{n_{11}n_{22}}{n_{12}n_{21}}, \quad (3)$$

where the notation in the rightmost expression represents the cell counts. From the above expression, we can see that odds ratio can always be computed regardless of whether the study is retrospective or prospective. Also, the odds ratio has the following relationship with the relative risk.

$$OR = RR \frac{1 - P(D|\bar{E})}{1 - P(D|E)}. \quad (4)$$

When the disease is rare, the probability of having the disease should be close to zero (by definition of ‘rare’), regardless of the exposure. Therefore, both $P(D|\bar{E})$ and $P(D|E)$ should be close to zero. In this case, the odds ratio and the relative risk should be very similar numerically. This means that in a case–control study, even if the prevalence of the disease $P(D)$ is unknown, we can still obtain the relative risk by approximating it with the odds ratio if we know that the disease is rare.

Catalogue of Parametric Tests

The classification ‘nonparametric statistical test’ is often used to refer to statistical tests involving parameters when the data is regarded as being nonquantitative (weaker than interval scale data). This catalogue therefore excludes tests based on ranks (*see Rank Based Inference*) but includes chi-square tests, which can be seen as tests involving differences in proportions even though they are often taken to be nonparametric.

One way to look at the definition of a parametric test is to note that a parameter is a measure taken from a population. Thus, the mean and standard deviation of data for a whole population are both parameters. Parametric tests make certain assumptions about the nature of parameters, including the appropriate probability distribution, which can be used to decide whether the result of a statistical test is significant. In addition, they can be used to find a **confidence interval** for a given parameter.

The types of tests given here have been categorized into those that compare means, those that compare variances, those that relate to correlation and regression, and those that deal with frequencies and proportions.

Comparing Means

z-tests

z-tests compare a statistic (or single score) from a sample with the expected value of that statistic in the population under the null hypothesis. The expected value of the statistic under H_0 (see entry on expected value) is subtracted from the observed value of the statistic and the result is divided by its standard deviation. When the sample statistic is based on more than a single score, then the standard deviation for that statistic is its standard error. Thus, this type of test can only be used when the expected value of the statistic and its standard deviation are known. The probability of a *z*-value is found from the standardized normal distribution, which has a mean of 0 and a standard deviation of 1 (*see Catalogue of Probability Density Functions*).

One-group *z*-test for a Single Score. In this version of the test, the equation is

$$z = \frac{x - \mu}{\sigma}, \quad (1)$$

where

x is the single score

μ is the mean for the scores in the population

σ is the standard deviation in the population

Example

Single score = 10

$$\mu = 5$$

$$\sigma = 2$$

$$z = \frac{10 - 5}{2} = 2.5.$$

Critical value for z at $\alpha = 0.05$ with a two-tailed test is 1.96.

Decision: reject H_0 .

One-group *z*-test for a Single Mean. This version of the test is a modification of the previous one because the distribution of means is the standard error of the mean: $\sigma/\sqrt{n}$, where n is the sample size.

The equation for this *z*-test is

$$z = \frac{m - \mu}{\left(\frac{\sigma}{\sqrt{n}}\right)}, \quad (2)$$

where

m is the mean in the sample

μ is the mean in the population

σ is the standard deviation in the population

n is the sample size

Example

$$m = 5.5$$

$$\mu = 5$$

$$\sigma = 2$$

$$n = 20$$

$$z = \frac{5.5 - 5}{\left(\frac{2}{\sqrt{20}}\right)} = 1.12.$$

The critical value for z with $\alpha = 0.05$ and a one-tailed test is 1.64.

Decision: fail to reject H_0 .

2 Catalogue of Parametric Tests

t Tests

t Tests form a family of tests that derive their probability from Student's *t* distribution (see **Catalogue of Probability Density Functions**). The shape of a particular *t* distribution is a function of the degrees of freedom. *t* Tests differ from *z*-tests in that they estimate the population standard deviation from the standard deviation(s) of the sample(s). Different versions of the *t* Test have different ways in which the degrees of freedom are calculated.

One-group *t* Test. This test is used to compare a mean from a sample with that of a population or hypothesized value from the population, when the standard deviation for the population is not known. The null hypothesis is that the sample is from the (hypothesized) population (that is, $\mu = \mu_h$, where μ is the mean of the population from which the sample came and μ_h is the mean of the population with which it is being compared).

The equation for this version of the *t* Test is

$$t = \frac{m - \mu_h}{\left(\frac{s}{\sqrt{n}}\right)}, \quad (3)$$

where

- m is the mean of the sample
- μ_h is the mean or assumed mean for the population
- s is the standard deviation of the sample
- n is the sample size.

Degrees of freedom:

In this version of the *t* Test, $df = n - 1$.

Example

$$\begin{aligned} m &= 9, \mu_h = 7 \\ s &= 3.2, n = 10 \\ df &= 9 \\ t_{(9)} &= 1.98. \end{aligned}$$

The critical *t* with $df = 9$ at $\alpha = 0.05$ for a two-tailed test is 2.26.

Decision: fail to reject H_0 .

Between-subjects *t* Test. This test is used to compare the means of two different samples. The null hypothesis is $\mu_1 = \mu_2$ (i.e., $\mu_1 - \mu_2 = 0$, where μ_1 and μ_2 are the means of the two populations from which the samples come).

There are two versions of the equation for this test – one when the variances of the two populations are homogeneous, where the variances are pooled, and one when the variances are heterogeneous and the variances are entered separately into the equation.

Homogeneous variance

$$t = \frac{m_1 - m_2}{\sqrt{pv \times \left(\frac{1}{n_1} + \frac{1}{n_2}\right)}}, \quad (4)$$

where m_1 and m_2 are the sample means of groups 1 and 2 respectively n_1 and n_2 are the sample sizes of the two groups and pv is the pooled variance

$$pv = \frac{(n_1 - 1) \times s_1^2 + (n_2 - 1) \times s_2^2}{n_1 + n_2 - 2}, \quad (5)$$

where s_1^2 & s_2^2 are the variances of groups 1 and 2. When the two group sizes are the same this simplifies to

$$t = \frac{m_1 - m_2}{\sqrt{\frac{s_1^2 + s_2^2}{n}}}, \quad (6)$$

where n is the sample size of each group.

Heterogeneous variances

$$t = \frac{m_1 - m_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}}, \quad (7)$$

Degrees of freedom:

Homogeneous variance

$$df = n_1 + n_2 - 2. \quad (8)$$

Heterogeneous variance

$$df = \frac{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)^2}{\frac{\left(\frac{s_1^2}{n_1}\right)^2}{n_1 - 1} + \frac{\left(\frac{s_2^2}{n_2}\right)^2}{n_2 - 1}}. \quad (9)$$

Example of groups with homogeneous variance

$$\begin{aligned} m_1 &= 5.3, m_2 = 4.1 \\ n_1 &= n_2 = 20 \\ s_1^2 &= 1.3, s_2^2 = 1.5 \end{aligned}$$

$$\text{df} = 38$$

$$t_{(38)} = 3.21.$$

The critical t for a two-tailed probability with $\text{df} = 38$, at $\alpha = 0.05$ is 2.02.

Decision: reject H_0 .

Within-subjects t Test. This version of the t Test is used to compare two means that have been gained from the same sample, for example, anxiety levels before a treatment and after a treatment, or from two matched samples. For each person, a difference score is found between the two scores, which that person has provided. The null hypothesis is that the mean of the difference scores is 0 ($\mu_d = 0$, where μ_d is the mean of the difference scores in the population).

The equation for this test is

$$t = \frac{m_d}{\left(\frac{s_d}{\sqrt{n}}\right)}, \quad (10)$$

where

m_d is the mean of the difference scores

s_d is the standard deviation of the difference scores

n is the number of difference scores.

Degrees of freedom:

In this version of the t Test, the df are $n - 1$.

Example

$$m_1 = 153.2, m_2 = 145.1, m_d = 8.1$$

$$s_d = 14.6, n = 20$$

$$\text{df} = 19$$

$$t_{(19)} = 2.48.$$

The critical t for $\text{df} = 19$ at $\alpha = 0.05$ for a one-tailed probability is 1.729.

Decision: reject H_0 .

ANOVA

Analysis of variance (ANOVA) allows the comparison of the means of more than two different conditions to be compared at the same time in a single omnibus test. As an example, researchers might wish to look at the relative effectiveness of two treatments for a particular phobia. They could compare a measure of anxiety from people who have received one treatment with those who received the other treatment and with those who received no treatment (the

control group). The null hypothesis, which is tested, is that the means from different ‘treatments’ are the same in the population. Thus, if three treatments are being compared, the null hypothesis would be $\mu_1 = \mu_2 = \mu_3$, where μ denotes the mean for the measure in the population. ANOVA partitions the overall variance in a set of data into different parts.

The statistic that is created from an ANOVA is the F -ratio. It is the ratio of an estimate of the variance between the conditions and an estimate of the variance, which is not explicable in terms of differences between the conditions, that which is due to individual differences (sometimes referred to as *error*).

$$F = \frac{\text{variance between conditions}}{\text{variance due to individual differences}}. \quad (11)$$

If the null hypothesis is true, then these two variance estimates will both be due to individual differences and F will be close to 1. If the values from the different treatments do differ, then F will tend to be larger than 1. The probability of an F -value is found from the F distribution (see **Catalogue of Probability Density Functions**). The value of F , which is statistically significant, depends on the degrees of freedom. In this test, there are two different degrees of freedom that determine the shape of the F distribution: the df for the variance between conditions and the df for the error.

The variance estimates are usually termed the *mean squares*. These are formed by dividing a sum of squared deviations from a mean (usually referred to as the *sum of squares*) by the appropriate degrees of freedom.

The F -ratio is formed in different ways, depending on aspects of the design such as whether it is a between-subjects or a within-subjects design. In addition, the F -value will be calculated on a different basis if the independent variables are fixed or random (see **Fixed and Random Effects**) and whether, in the case of between-subjects designs with unequal sample sizes (unbalanced designs), the weighted or unweighted means are used. The examples given here are for fixed independent variables (other than participants) and weighted means. For variations on the calculations, see [8]. The methods of calculation shown will be ones designed to explicate what the equation is doing rather than the computationally simplest version.

4 Catalogue of Parametric Tests

One-way ANOVA

One-way Between-subjects ANOVA. This version of the test partitions the total variance into two components: between the conditions (between-groups) and within groups (the error).

Sums of squares

The sum of squares between the groups (SS_{bg}) is formed from

$$SS_{bg} = \sum [n_i \times (m_i - m)^2], \quad (12)$$

where

n_i is the sample size in group i

m_i is the mean of group i

m is the overall mean.

The sum of squares within the groups (SS_{wg}) is formed from

$$SS_{wg} = \sum \sum (x_{ij} - m_i)^2, \quad (13)$$

where

x_{ij} is the j th data point in group i

m_i is the mean in group i .

Degrees of freedom

The df for between-groups is one fewer than the number of groups:

$$df_{bg} = k - 1, \quad (14)$$

where k is the number of groups.

The degrees of freedom for within groups is the total sample size minus the number of groups:

$$df_{wg} = N - k, \quad (15)$$

where

N is the total sample size

k is the number of groups

Mean squares

The mean squares (MS) are formed by dividing the sum of squares by the appropriate degrees of freedom:

$$MS_{bg} = \frac{SS_{bg}}{df_{bg}}. \quad (16)$$

$$MS_{wg} = \frac{SS_{wg}}{df_{wg}}. \quad (17)$$

Table 1 The scores and group means of three groups in a between-subjects design

	Group		
	A	B	C
	2	5	7
	3	7	5
	3	5	6
	3	5	4
	1	5	4
	1	4	7
Mean (m_i)	2.167	5.167	5.500

F-ratio

The F -ratio is formed by

$$F = \frac{MS_{bg}}{MS_{wg}}. \quad (18)$$

Example

Three groups each with six participants are compared (Table 1).

Overall mean (m) = 4.278

$$SS_{bg} = \sum [6 \times (m_i - 4.278)^2] = 40.444$$

$$SS_{wg} = 19.167$$

$$df_{bg} = 3 - 1 = 2$$

$$df_{wg} = 18 - 3 = 15$$

$$MS_{bg} = \frac{40.444}{2} = 20.222$$

$$MS_{wg} = \frac{19.167}{15} = 1.278$$

$$F_{(2,15)} = \frac{20.222}{1.278} = 15.826.$$

The critical F -value for $\alpha = 0.05$, with df of 2 and 15 is 3.68.

Decision: Reject H_0 .

One-way Within-subjects ANOVA. Because each participant provides a value for every condition in this design, it is possible to partition the overall variance initially into two parts: that which is between-subjects and that which is within-subjects. The latter can then be further divided, to form the elements necessary for the F -ratio, into between-conditions and that which is subjects within conditions (the residual), with the final one being the error term for the F -ratio. This is a more efficient test because

the between-subjects variance is taken out of the calculation, and so the error variance estimate is smaller than in the equivalent between-subjects ANOVA.

Sums of squares

The total sum of squares (SS_{Total}) is calculated from

$$SS_{\text{Total}} = \sum \sum (x_{ip} - m)^2, \quad (19)$$

where x_{ip} is the score of participant p in condition i . The between-subjects sum of squares (SS_S) is calculated from

$$SS_S = k \times \sum (m_p - m)^2, \quad (20)$$

where

k is the number of conditions
 m_p is the mean for participant p across the conditions
 m is the overall mean.

The within-subjects sum of squares (SS_{ws}) is found from

$$SS_{\text{ws}} = \sum \sum (x_{ip} - m_p)^2, \quad (21)$$

where

x_{ip} is the value provided by participant p in condition i
 m_p is the mean of participant p across all the conditions.

In words, for each participant, find the deviation between that person's score on each condition from that person's mean score. Square the deviations and sum them for that person. Find the sum of the sums.

The between-conditions sum of squares (SS_{bc}) is calculated the same way as the between-groups sum of squares in the between-subjects design, except that because the sample size in each condition will be the same, the multiplication by the sample size can take place after the summation:

$$SS_{\text{bc}} = n \times \sum (m_i - m)^2. \quad (22)$$

The residual sum of squares (SS_{res}) can be found by subtracting SS_{bc} from SS_{ws}

$$SS_{\text{res}} = SS_{\text{ws}} - SS_{\text{bc}}. \quad (23)$$

Degrees of freedom

The degrees of freedom for the total (df_{Total}) are found from

$$df_{\text{Total}} = (n \times k) - 1, \quad (24)$$

where

n is the sample size

k is the number of conditions.

The df for between subjects (df_S) is found from

$$df_S = n - 1, \quad (25)$$

where n is the sample size.

The df for between the conditions (df_{bc}) is found from

$$df_{\text{bc}} = k - 1, \quad (26)$$

where k is the number of conditions.

The df for the residual (df_{res}) is found from

$$df_{\text{res}} = df_{\text{Total}} - (df_{\text{bc}} + df_S). \quad (27)$$

Mean squares

The mean squares for between-conditions (MS_{bc}) is found from

$$MS_{\text{bc}} = \frac{SS_{\text{bc}}}{df_{\text{bc}}}. \quad (28)$$

The mean squares for the residual (MS_{res}) is found from

$$MS_{\text{res}} = \frac{SS_{\text{res}}}{df_{\text{res}}}. \quad (29)$$

F -ratio

The F -ratio is formed from

$$F = \frac{MS_{\text{bc}}}{MS_{\text{res}}}. \quad (30)$$

Example

Five participants provide scores on four different conditions (Table 2).

The overall mean is 10.2.

Sums of squares

$$SS_{\text{Total}} = 47.2$$

$$SS_S = 3.2$$

$$SS_{\text{ws}} = 44$$

$$SS_{\text{bc}} = 5.2$$

$$SS_{\text{res}} = 44 - 5.2 = 38.8$$

6 Catalogue of Parametric Tests

Table 2 The scores of the five participants in four conditions of a within-subjects design with means for conditions and participants

Participant	Condition				Mean
	1	2	3	4	
1	11	9	12	10	10.5
2	10	10	9	9	9.5
3	10	13	11	8	10.5
4	8	10	13	9	10
5	13	9	9	11	10.5
Mean	10.4	10.2	10.8	9.4	

Degrees of freedom

$$df_{\text{Total}} = (5 \times 4) - 1 = 19$$

$$df_{\text{S}} = 5 - 1 = 4$$

$$df_{\text{ws}} = 19 - 4 = 15$$

$$df_{\text{bc}} = 4 - 1 = 3$$

$$df_{\text{res}} = 19 - (3 + 4) = 12$$

Mean squares

$$MS_{\text{bc}} = \frac{5.2}{3} = 1.733, MS_{\text{res}} = \frac{38.8}{12} = 3.233$$

F-ratio

$$F_{(3,12)} = 0.536$$

The critical value of *F* for $\alpha = 0.05$ with df of 3 and 12 is 3.49.

Decision: fail to reject H_0 .

Multiway ANOVA

When there is more than one independent variable (IV), the way in which these variables work together can be investigated to see whether some act as moderators for others. An example of a design with two independent variables would be if researchers wanted to test whether the effects of different types of music (jazz, classical, or pop) on blood pressure might vary, depending on the age of the listeners. The moderating effects of age on the effects of music might be indicated by an interaction between age and music type. In other words, the pattern of the link between blood pressure and music type differed between the two age groups. Therefore, an ANOVA with two independent variables will have three *F*-ratios, each of which is testing a different

null hypothesis. The first will ignore the presence of the second independent variable and test the main effect of the first independent variable, such that if there were two conditions in the first IV, then the null hypothesis would be $\mu_1 = \mu_2$, where μ_1 and μ_2 are the means in the two populations for the first IV. The second *F*-ratio would test the second null hypothesis, which would refer to the main effect of the second IV with the existence of the first being ignored. Thus, if there were two conditions in the second IV, then the second H_0 would be $\mu_a = \mu_b$ where μ_a and μ_b are the means in the population for the second IV. The third *F*-ratio would address the third H_0 , which would relate to the interaction between the two IVs. When each IV has two levels, the null hypothesis would be $\mu_{a1} - \mu_{a2} = \mu_{b1} - \mu_{b2}$, where the μ_{a1} denotes the mean for the combination of the first condition of the first IV and the first condition of the second IV.

Examples are only given here of ANOVAs with two IVs. For more complex designs, there will be higher-order interactions as well. When there are *k* IVs, there will be 2, 3, 4, ..., *k* way interactions, which can be tested. For details of such designs, see [4].

Multiway Between-subjects ANOVA. This version of ANOVA partitions the overall variance into four parts: the main effect of the first IV, the main effect of the second IV, the interaction between the two IVs, and the error term, which is used in all three *F*-ratios.

Sums of squares

The Total sum of squares (SS_{Total}) is calculated from

$$SS_{\text{Total}} = \sum \sum \sum (x_{ijp} - m)^2, \quad (31)$$

where x_{ijp} is the score provided by participant *p* in condition *i* of IV₁ and condition *j* of IV₂. A simpler description is that it is the sum of the squared deviations of each participant's score from the overall mean.

The sum of squares for the first IV (SS_A) is calculated from

$$SS_A = \sum [n_i \times (m_i - m)^2], \quad (32)$$

where

n_i is the sample size in condition *i* of the first IV

m_i is the mean in condition *i* of the first IV

m is the overall mean.

The sum of squares for the second IV (SS_B) is calculated from

$$SS_B = \sum [n_j \times (m_j - m)^2], \quad (33)$$

where

n_j is the sample size in condition j of the second IV

m_j is the mean of condition j of the second IV

m is the overall mean.

The interaction sum of squares (SS_{AB}) can be found via finding the between-cells sum of squares ($SS_{b,cells}$), where a cell refers to the combination of conditions in the two IVs: for example, first condition of IV₁ and the first condition of IV₂. $SS_{b,cells}$ is found from

$$SS_{b,cells} = \sum \sum [n_{ij} \times (m_{ij} - m)^2], \quad (34)$$

where n_{ij} is the sample size in the combination of condition j of IV₂ and condition i of IV₁,

m_{ij} is the mean of the participants in the combination of condition j of IV₂ and condition i of IV₁,

m is the overall mean.

$$SS_{AB} = SS_{b,cells} - (SS_A + SS_B). \quad (35)$$

The sum of squares for the residual (SS_{res}) can be found from

$$SS_{res} = SS_{Total} - (SS_A + SS_B + SS_{AB}). \quad (36)$$

Degrees of freedom

The total degrees of freedom (df_{Total}) are found from

$$df_{Total} = N - 1, \quad (37)$$

where N is the total sample size.

The degrees of freedom for each main effect (for example df_A) are found from

$$df_A = k - 1, \quad (38)$$

where k is the number of conditions in that IV.

The interaction degrees of freedom (df_{AB}) are found from

$$df_{AB} = df_A \times df_B, \quad (39)$$

where df_A and df_B are the degrees of freedom of the two IVs.

The degrees of freedom for the residual (df_{res}) are calculated from

$$df_{res} = df_{Total} - (df_A + df_B + df_{AB}). \quad (40)$$

Mean Squares

Each mean square is found by dividing the sum of squares by the appropriate df. For example, the mean square for the interaction (MS_{AB}) is found from

$$MS_{AB} = \frac{SS_{AB}}{df_{AB}}. \quad (41)$$

F-ratios

Each *F*-ratio is found by dividing a given mean square by the mean square for the residual. For example, the *F*-ratio for the interaction is found from

$$F = \frac{MS_{AB}}{MS_{res}}. \quad (42)$$

Example

Twenty participants are divided equally between the four combinations of two independent variables, each of which has two conditions (Table 3).

Overall mean = 8.2

Sums of squares

$$SS_{Total} = 139.2$$

$$SS_A = 51.2$$

$$SS_B = 5.0$$

$$SS_{b,cells} = 56.4$$

$$SS_{AB} = 56.4 - (51.2 + 5.0) = 0.2$$

$$SS_{res} = 139.2 - (51.2 + 5.0 + 0.2) = 82.8$$

Degrees of freedom

$$df_{Total} = 20 - 1 = 19$$

$$df_A = 2 - 1 = 1$$

$$df_B = 2 - 1 = 1$$

Table 3 The scores and group means of participants in a 2-way, between-subjects design

IV ₁ (A)	1		2	
IV ₂ (B)	1	2	1	2
	9	7	6	4
	11	10	4	4
	10	14	9	10
	10	10	5	9
	7	10	6	9
Means	9.4	10.2	6	7.2

8 Catalogue of Parametric Tests

$$df_{AB} = 1 \times 1 = 1$$

$$df_{res} = 19 - (1 + 1 + 1) = 16$$

Mean squares

$$MS_A = \frac{51.2}{1} = 51.2$$

$$MS_B = \frac{5}{1} = 5$$

$$MS_{AB} = \frac{0.2}{1} = 0.2$$

$$MS_{res} = \frac{82.8}{16} = 5.175$$

F-ratios

$$F_{A(1,16)} = \frac{51.2}{5.175} = 9.89$$

The critical value for *F* at $\alpha = 0.05$ with df of 1 and 16 is 4.49.

Decision: Reject H_0

$$F_{B(1,16)} = \frac{5}{5.175} = 0.97.$$

Decision: Fail to reject H_0

$$F_{AB(1,16)} = \frac{0.2}{5.175} = 0.04.$$

Decision: Fail to reject H_0 .

Multiway Within-subjects ANOVA. As with other within-subjects ANOVAs, this test partitions the variance into that which is between-subjects and that which is within-subjects. The latter is further partitioned in such a way that the variance for IVs, the interaction between IVs, and the error terms are all identified. Unlike the between-subjects equivalent, there is a different error term for each IV and the interaction (*see Repeated Measures Analysis of Variance*).

Sums of squares

The total sum of squares (SS_{Total}) is calculated from

$$SS_{Total} = \sum \sum \sum (x_{ijp} - m)^2, \quad (43)$$

where x_{ijp} is the score provided by participant p in condition i of IV₁ and condition j of IV₂

m is the overall mean.

A simpler description is that it is the sum of the squared deviations of each participant's score in each condition of each IV from the overall mean.

The between-subjects sum of squares (SS_S) is calculated from

$$SS_S = k_1 \times k_2 \times \sum (m_p - m)^2, \quad (44)$$

where

k_1 and k_2 are the number of conditions in each IV
 m_p is the mean for participant p across all the conditions
 m is the overall mean.

The within-subjects sum of squares (SS_{ws}) is calculated from

$$SS_{ws} = \sum \sum \sum (x_{ijp} - m_p)^2, \quad (45)$$

where

x_{ijp} is the value provided by participant p in condition i of IV₁ and condition j of IV₂
 m_p is the mean of participant p across all the conditions.

In words, for each participant, find the deviation between that person's score on each condition from that person's mean score. Square the deviations and sum them for that person. Find the sum of the sums. The sum of squares for the main effect of IV₁ (SS_A) is calculated from

$$SS_A = n \times k_2 \times \sum (m_i - m)^2, \quad (46)$$

where

n is the sample size
 k_2 is the number of conditions in IV₂
 m_i is the mean for condition i of IV₁
 m is the overall mean.

The sum of squares for IV₁ by subjects cell ($SS_{A \text{ by } s \text{ cell}}$) is calculated from

$$SS_{A \text{ by } s \text{ cell}} = k_1 \times \sum (m_{ip} - m)^2, \quad (47)$$

where

k_1 is the number of conditions in IV₁
 m_{ip} is the mean for participant p for condition i of IV₁.

The sum of squares for IV₁ by subjects (SS_{AS}), which is the error term, is calculated from

$$SS_{AS} = SS_{A \text{ by } s \text{ cell}} - (SS_A + SS_S). \quad (48)$$

(SS_B and its error term SS_{BS} are calculated in an analogous fashion.)

The sum of squares for cells ($SS_{b,cells}$) is found from

$$SS_{b,cells} = n \times \sum \sum (m_{ij} - m)^2, \quad (49)$$

where

- n is the sample size
- m_{ij} is the mean for the combination of condition j of IV_1 and condition i of IV_2
- m is the overall mean.

The sum of squares for the interaction between IV_1 and IV_2 (SS_{AB}) is calculated from

$$SS_{AB} = SS_{b,cells} - (SS_A + SS_B). \quad (50)$$

The sum of squares for the error term for the interaction IV_1 by IV_2 by subjects (SS_{ABS}) is found from

$$SS_{ABS} = SS_{Total} - (SS_A + SS_B + SS_{AB} + SS_{AS} + SS_{BS} + SS_S). \quad (51)$$

Degrees of freedom

The total degrees of freedom is found from

$$df_{Total} = n \times k_1 \times k_2 - 1, \quad (52)$$

where n is the sample size

k_1 and k_2 are the number of conditions in IV_1 and IV_2 respectively

$$df_S = n - 1. \quad (53)$$

$$df_A = k_1 - 1. \quad (54)$$

$$df_B = k_2 - 1. \quad (55)$$

$$df_{AB} = df_A \times df_B. \quad (56)$$

$$df_{AS} = df_A \times df_S. \quad (57)$$

$$df_{BS} = df_B \times df_S. \quad (58)$$

$$df_{ABS} = df_{AB} \times df_S. \quad (59)$$

Mean squares

$$MS_A = \frac{SS_A}{df_A}, \quad MS_B = \frac{SS_B}{df_B}, \quad MS_{AB} = \frac{SS_{AB}}{df_{AB}},$$

$$MS_{AS} = \frac{SS_{AS}}{df_{AS}}, \quad MS_{BS} = \frac{SS_{BS}}{df_{BS}}, \quad (60)$$

$$MS_{ABS} = \frac{SS_{ABS}}{df_{ABS}}. \quad (61)$$

Table 4 The scores and group means of participants in a 2-way, within-subjects design

IV ₁ (A)	1		2	
IV ₂ (B)	1	2	1	2
1	12	15	15	16
2	10	12	17	14
3	15	12	12	19
4	12	14	14	19
5	12	11	13	14
Mean	12.2	12.8	14.2	16.4

F -ratios

$$F_A = \frac{MS_A}{MS_{AS}}, \quad F_B = \frac{MS_B}{MS_{BS}}, \quad F_{AB} = \frac{MS_{AB}}{MS_{ABS}}. \quad (62)$$

Example

Five participants provide scores for two different IVs each of which has two conditions (Table 4).

$$SS_{Total} = 115.8, \quad SS_S = 15.3, \quad SS_A = 39.2, \quad SS_{AS} = 5.3, \quad SS_B = 9.8, \quad SS_{BS} = 10.7, \quad SS_{AB} = 3.2, \quad SS_{ABS} = 32.3$$

$$df_S = 5 - 1 = 4, \quad df_A = 2 - 1 = 1, \quad df_{AS} = 1 \times 4 = 4, \quad df_B = 2 - 1 = 1, \quad df_{BS} = 1 \times 4 = 4, \quad df_{AB} = 1 \times 1 = 1, \quad df_{ABS} = 1 \times 4 = 4$$

$$MS_A = \frac{39.2}{1} = 39.2, \quad MS_{AS} = \frac{5.3}{4} = 1.325,$$

$$MS_B = \frac{9.8}{1} = 9.8, \quad MS_{BS} = \frac{10.7}{4}$$

$$= 2.675, \quad MS_{AB} = \frac{3.2}{1}, \quad MS_{ABS} = \frac{32.3}{4}$$

$$= 8.075$$

$$F_{A(1,4)} = \frac{39.2}{1.325} = 29.58.$$

The critical value of F at $\alpha = 0.05$ with df of 1 and 4 is 7.71.

Decision: Reject H_0

$$F_{B(1,4)} = \frac{9.8}{2.675} = 3.66.$$

Decision: Fail to reject H_0

$$F_{AB(1,4)} = \frac{3.2}{8.075} = 0.56.$$

Decision: Fail to reject H_0 .

Multiway Mixed ANOVA. Mixed has a number of meanings within statistics. Here it is being used to

mean designs that contain both within- and between-subjects independent variables. For the description of the analysis and the example data, the first independent variable will be between-subjects and the second within-subjects.

The overall variance can be partitioned into that which is between-subjects and that which is within-subjects. The first part is further subdivided into the variance for IV_1 and its error term (within groups). The second partition is subdivided into the variance for IV_2 , for the interaction between IV_1 and IV_2 and the error term for both (IV_1 by IV_2 by subjects).

Sums of squares

The total sum of squares is given by

$$SS_{\text{Total}} = \sum \sum (x_{jp} - m)^2, \quad (63)$$

where x_{jp} is the score provided by participant p in condition j of IV_2 .

A simpler description is that it is the sum of the squared deviations of each participant's score in each condition of IV_2 from the overall mean.

The between-subjects sum of squares (SS_S) is calculated from

$$SS_S = k_2 \times \sum (m_p - m)^2, \quad (64)$$

where

k_2 is the number of conditions in IV_2

m_p is the mean for participant p across all the conditions in IV_2

m is the overall mean.

The within-subjects sum of squares (SS_{ws}) is calculated from

$$SS_{ws} = \sum \sum (x_{jp} - m_p)^2, \quad (65)$$

where

x_{jp} is the value provided by participant p in condition j of IV_2

m_p is the mean of participant p across all the conditions.

The sum of squares for IV_1 (SS_A) is given by

$$SS_A = k_2 \times \sum [n_i \times (m_i - m)^2], \quad (66)$$

where

k_2 is the number of conditions in IV_2

n_i is the size of the sample in condition i of IV_1
 m_i is the mean for all the scores in condition i of IV_1
 m is the overall mean.

The sum of squares for within groups (SS_{wg}) is given by:

$$SS_{wg} = SS_S - SS_A. \quad (67)$$

The sum of squares for between cells (SS_{bc}) is given by

$$SS_{bc} = \sum \left[n_i \times \sum (m_{ij} - m)^2 \right], \quad (68)$$

where

n_i is the sample size in condition i of IV_1
 m_{ij} is the mean of the combination of condition i of IV_1 and condition j of IV_2
 m is the overall mean.

The sum of squares for the interaction between IV_1 and IV_2 (SS_{AB}) is given by

$$SS_{AB} = SS_{bc} - (SS_A + SS_B). \quad (69)$$

The sum of squares for IV_2 by subjects within groups ($SS_{B.s(gps)}$) is given by

$$SS_{B.s(gps)} = SS_{ws} - (SS_B + SS_{AB}). \quad (70)$$

Degrees of freedom

$df_{\text{Total}} = N \times k_2 - 1$, where N is the sample size,

$df_A = k_1 - 1$, $df_B = k_2 - 1$, $df_{AB} = df_A \times df_B$,

$df_{wg} = \sum (n_i - 1)$, where n_i is the sample in condition i of IV_1 , $df_{B.s(gps)} = df_B \times df_{wg}$. (71)

Mean squares

$$\begin{aligned} MS_A &= \frac{SS_A}{df_A}, MS_{wg} = \frac{SS_{wg}}{df_{wg}}, MS_B = \frac{SS_B}{df_B}, \\ MS_{AB} &= \frac{SS_{AB}}{df_{AB}}, MS_{bg} = \frac{SS_{bg}}{df_{bg}}, MS_{B.s(gps)} \\ &= \frac{SS_{B.s(gps)}}{df_{B.s(gps)}}. \end{aligned} \quad (72)$$

F-ratios

$$F_A = \frac{MS_A}{MS_{wg}}, F_B = \frac{MS_B}{MS_{B.s(gps)}}, F_{AB} = \frac{MS_{AB}}{MS_{B.s(gps)}}. \quad (73)$$

Table 5 The scores of participants in a 2-way, mixed design

Participant	Condition of IV ₁ (A)	Condition of IV ₂ (B)	
		1	2
1	1	11	9
2	1	13	8
3	1	12	11
4	1	10	11
5	1	10	10
6	2	10	12
7	2	11	12
8	2	13	10
9	2	9	13
10	2	10	11

Example

Five participants provided data for condition 1 of IV₁ and five provided data for condition 2 of IV₁. All participants provided data for both conditions of IV₂ (Table 5).

Sum of squares

$$\begin{aligned} SS_S &= 6.2, SS_{ws} = 31, SS_A = 1.8, SS_{wg} = 4.4, \\ SS_{b,cell} &= 9.2, SS_B = 0.2, SS_{AB} = 9.2 - \\ &(1.8 + 0.2) = 7.2, SS_{B.s(gps)} = 31 - (0.2 + \\ &7.2) = 23.6 \end{aligned}$$

Degrees of freedom

$$\begin{aligned} df_A &= 2 - 1 = 1, \quad df_{wg} = (5 - 1) + (5 - 1) = 8, \\ df_B &= 2 - 1 = 1, \quad df_{AB} = 1 \times 1 = 1, \quad df_{B.s(gps)} \\ &= 1 \times 8 = 8 \end{aligned}$$

Mean squares

$$\begin{aligned} MS_A &= 1.8, MS_{wg} = 0.55, MS_B = 0.2, MS_{AB} = 7.2, \\ MS_{B.s(gps)} &= 2.95 \end{aligned}$$

F-ratios

$$F_{A(1,8)} = \frac{1.8}{0.55} = 3.27$$

The critical value for F at $\alpha = 0.05$ with df of 1 and 8 is 5.32.

Decision: Fail to reject H_0

$$F_{B(1,8)} = \frac{0.2}{2.95} = 0.07.$$

Decision: Fail to reject H_0

$$F_{AB(1,8)} = \frac{7.2}{2.95} = 2.44.$$

Decision: Fail to reject H_0 .

Extensions of ANOVA. The analysis of variance can be extended in a number of ways. Effects with several degrees of freedom can be decomposed into component effects using comparisons of treatment means, including trend tests. **Analyses of covariance** can control statistically for the effects of potentially confounding variables. **Multivariate analyses of variance** can simultaneously test effects of the same factors on different dependent variables.

Comparing Variances

F test for Difference Between Variances

Two Independent Variances. This test compares two variances from different samples to see whether they are significantly different. An example of its use could be where we want to see whether a sample of people's scores on one test were more variable than a sample of people's scores on another test.

The equation for the F test is

$$F = \frac{s_1^2}{s_2^2}, \quad (74)$$

where the variance in one sample is divided by the variance in the other sample.

If the research hypothesis is that one particular group will have the larger variance, then that should be treated as group 1 in this equation. As usual, an F -ratio close to 1 would suggest no difference in the variances of the two groups. A large F -ratio would suggest that group 1 has a larger variance than group 2, but it is worth noting that a particularly small F -ratio, and therefore a probability close to 1, would suggest that group 2 has the larger variance.

Degrees of freedom

The degrees of freedom for each variance are 1 fewer than the sample size in that group.

Example

Group 1
Variance: 16
Sample size: 100

Group 2
Variance: 11
Sample size: 150

$$F = \frac{16}{11} = 1.455$$

Degrees of freedom

Group 1 df = 100 - 1 = 99; group 2 df = 150 - 1 = 149

The critical value of F with df of 99 and 149 for $\alpha = 0.05$ is 1.346.

Decision: Reject H_0 .

Two Correlated Variances. This version of the test compares two variances that have been derived from the same group. The F test has to take account of the degree to which the two sets of data are correlated. Although other equations exist, which would produce an equivalent probability, the version here gives a statistic for an F -ratio.

The F test uses the equation:

$$F = \frac{(s_1^2 - s_2^2)^2 \times (n - 2)}{4 \times s_1^2 \times s_2^2 \times (1 - r_{12}^2)}, \quad (75)$$

where

s^2 refers to variance

r_{12} is the correlation between the two variables

n is the sample size.

Degrees of freedom

The test has df 1 and $n - 2$.

Example

Sample size: 50

Variance in variable 1: 50

Variance in variable 2: 35

Correlation between the two variables: 0.7

Error df = 50 - 2 = 48

$$F_{(1,48)} = \frac{(50 - 35)^2 \times (50 - 2)}{4 \times 50 \times 35 \times (1 - (.7)^2)} = 3.025$$

The critical value for F with df = 1 and 48 for $\alpha = 0.05$ is 4.043.

Decision: Fail to reject H_0 .

K Independent Variances. The following procedure was devised by Bartlett [2] to test differences between the variances from more than two independent groups.

The finding of the statistic B (which can be tested with the chi-squared distribution) involves a number of stages. The first stage is to find an estimate of the

overall variance (S^2). This is achieved by multiplying each sample variance by its related df, which is one fewer than the size of that sample, summing the results and dividing that sum by the sum of all the df:

$$S^2 = \frac{\sum [(n_i - 1) \times s_i^2]}{N - k}, \quad (76)$$

where

n_i is the sample for the i th group

s_i^2 is the variance in group i

N is the total sample size

k is the number of groups.

Next, we need to calculate a statistic known as C , using

$$C = 1 + \frac{1}{3 \times (k - 1)} \times \left[\sum \left(\frac{1}{n_i - 1} \right) - \frac{1}{N - k} \right]. \quad (77)$$

We are now in a position to calculate B :

$$B = \frac{2.3026}{C} \times \left[(N - k) \times \log(S^2) - \sum \{ (n_i - 1) \times \log(s_i^2) \} \right], \quad (78)$$

where log means take the logarithm to the base 10.

Degrees of freedom

df = $k - 1$, where k is the number of groups.

(79)

Kanji [5] cautions against using the chi-square distribution when the sample sizes are smaller than 6 and provides a table of critical values for a statistic derived from B when this is the case.

Example

We wish to compare the variances of three groups: 2.62, 3.66, and 2.49, with each group having the same sample size: 10.

$$N = 30, k = 3, N - k = 27, C = 0.994$$

$$S^2 = 2.923, \log(s_1^2) = 0.418, \log(s_2^2) = 0.563,$$

$$\log(s_3^2) = 0.396$$

$$\log(S^2) = 0.466,$$

$$(N - k) \times \log(S^2) = 12.579$$

$$\sum [(n_i - 1) \times \log(s_i^2)] = 12.402$$

$$B = 0.4098$$

$$df = 3 - 1 = 2$$

The critical value of chi-squared for $\alpha = 0.05$ for $df = 2$ is 5.99.

Decision: Fail to reject H_0

Correlations and Regression

t Test for a Single Correlation Coefficient. This test can be used to test the statistical significance of a correlation between two variables, for example, scores on two tests of mathematical ability. It makes the assumption under the null hypothesis that there is no correlation between these variables in the population. Therefore, the null hypothesis is $\rho = 0$, where ρ is the correlation in the population. The equation for this test is

$$t = \frac{r \times \sqrt{n-2}}{\sqrt{1-r^2}}, \quad (80)$$

where

r is the correlation in the sample
 n is the sample size.

Degrees of freedom

In this version of the t Test, $df = n - 2$, where n is the sample size.

Example

$$\begin{aligned} r &= 0.4, n = 15 \\ df &= 13 \\ t_{(13)} &= 1.57 \end{aligned}$$

Critical t for a two-tailed test with $\alpha = 0.05$ and $df = 13$ is 2.16.

Decision: fail to reject H_0 .

t Test for Partial Correlation. A partial correlation involves removing the shared variance between two variables, which may be explained by a third (or even more) other variable(s) (*see Partial Correlation Coefficients*). An example would be if the relationship between two abilities were being assessed in a sample of children. If the sample involves a range of ages, then any link between the two abilities may be an artifact of the link between each of them and age. Partial correlation would allow the relationship

between the two abilities to be evaluated with the relationship each has with age controlled for. The equation for a partial correlation is

$$r_{12.3} = \frac{r_{12} - r_{13} \times r_{23}}{\sqrt{(1-r_{13}^2)(1-r_{23}^2)}}, \quad (81)$$

where $r_{12.3}$ is the correlation between variables 1 and 2 with variable 3 partialled out, r_{12} is the Pearson Product Moment correlation coefficient between variables 1 and 2, r_{13} and r_{23} are the correlations between the two main variables and variable 3.

The process can be extended to partial out more than one variable [3]. Sometimes, partial correlations are described as being of a particular order. If one variable is being partialled out, the correlation is of order 1. This leads to the expression zero-order correlation, which is sometimes used to describe a correlation with no variables partialled out.

When testing the statistical significance of a partial correlation the null hypothesis is that there is no relationship between the two variables of interest when others have been partialled out. Thus for a partial correlation of order 1 the null hypothesis is $\rho_{12.3} = 0$.

The t Test for a partial correlation is

$$t = \frac{r \times \sqrt{n-2-k}}{\sqrt{1-r^2}}, \quad (82)$$

where

r is the partial correlation coefficient
 n is the sample size
 k is the number of variables that have been partialled out (the order of the correlation).

Degrees of freedom

For each variable to be partialled out, an extra degree of freedom is lost from the degrees of freedom, which would apply to the t Test for a correlation when no variable is being partialled out. Therefore, when one variable is being partialled out, $df = n - 2 - 1 = n - 3$.

Example

$$\begin{aligned} r_{12} &= 0.5, r_{13} = 0.3, r_{23} = 0.2 \\ n &= 20 \\ r_{12.3} &= 0.47 \end{aligned}$$

$$df = 20 - 2 - 1 = 17$$

$$t_{(17)} = 2.2$$

The critical value of t with $df = 17$ for a two-tailed test with $\alpha = 0.05$ is 2.11.

Decision: reject H_0 .

z-test for Correlation Where ρ Not Equal to 0.

This test compares a correlation in a sample with that in a population. A complication with this version of the test is that when the population value for the correlation (ρ) is not 0, the distribution of the statistic is not symmetrical. **Fisher** devised a transformation for ρ and for the correlation in the sample (r), which allows a z -test to be performed.

The equation for this test is

$$z = \frac{r' - \rho'}{\sqrt{\frac{1}{n-3}}}, \quad (83)$$

where

r' is the Fisher's transformation of r , the correlation in the sample

ρ' is the Fisher's transformation of ρ the correlation in the population

n is the sample size.

Example

$$r = 0.6$$

$$\rho = 0.4$$

$$n = 20$$

Fisher's transformation of r (r') = 0.693147

Fisher's transformation of ρ (ρ') = 0.423649

$$z = \frac{0.693147 - 0.423649}{\sqrt{\frac{1}{20-3}}} = 1.11$$

The critical value for z with $\alpha = 0.05$ for a two-tailed test is 1.96.

Decision: Fail to reject H_0 .

z-test for Comparison of Two Independent Correlations. As with the previous example of a z -test, this version requires the correlations to be transformed using Fisher's transformation.

The equation for z is

$$z = \frac{r'_1 - r'_2}{\sqrt{\frac{1}{n_1 - 1} + \frac{1}{n_2 - 1}}}, \quad (84)$$

where r'_1 and r'_2 are the Fisher's transformations of the correlations in the two samples

n_1 and n_2 are the sample sizes of the two samples

Example

Sample 1, $n = 30$, $r = 0.7$, Fisher's transformation = 0.867301

Sample 2, $n = 25$, $r = 0.5$, Fisher's transformation = 0.549306

$$z = \frac{0.867301 - 0.549306}{\sqrt{\frac{1}{30-1} + \frac{1}{25-1}}} = 1.15$$

The critical value for z with $\alpha = 0.05$ for a one-tailed test is 1.64.

Decision: Fail to reject H_0 .

z-test for Comparison of Two Nonindependent Correlations.

When the correlations to be compared are not from independent groups, the equations become more complicated. There are two types of correlation that we might want to compare. The first is where the two correlations involve one variable in common, for example, when we wish to see whether a particular variable is more strongly related to one variable than another. The second is where the variables in the two correlations are different. An example of the latter could be where we are interested in seeing whether two variables are more strongly related than two other variables. This version could also be used if we were measuring the same two variables on two different occasions to see whether the strength of their relationship had changed between the occasions. The tests given here come from Steiger [7].

One Variable in Common. Given a correlation matrix of three variables as in Table 6:

where we wish to compare the correlation between variables 1 and 2 (r_{21}) with that between variables 1 and 3 (r_{31}).

Initially, we need to find what is called the determinant of this matrix, usually shown as $|R|$

Table 6 The correlation matrix for three variables showing the symbol for each correlation

Variable	Variable		
	1	2	3
1	1		
2	r_{21}	1	
3	r_{31}	r_{32}	1

where

$$|R| = [1 - (r_{21})^2 - (r_{31})^2 - (r_{32})^2] + (2 \times r_{21} \times r_{31} \times r_{32}). \quad (85)$$

Next, we need the mean of the two correlations that we are comparing ($\bar{r}$)

These values can now be put into a t Test:

$$t = \sqrt{\frac{(n-1) \times (1+r_{32})}{2 \times \left(\frac{n-1}{n-3}\right) \times |R| + \bar{r}^2 \times (1-r_{32})^3}}. \quad (86)$$

where n is the sample size.

Degrees of freedom

$$df = n - 3. \quad (87)$$

Example

Data on three variables are collected from 20 people. The correlation matrix is shown in Table 7:

$$\begin{aligned} |R| &= 0.832 \\ \bar{r} &= 0.136 \\ n &= 20 \\ df &= 20 - 3 = 17 \\ t_{(17)} &= -1.46 \end{aligned}$$

The critical value of t with $\alpha = 0.05$, using a two-tailed test, for $df = 17$ is 2.11.

Decision: Fail to reject H_0 .

Table 7 The correlation matrix of three variables

	1	2	3
1	1		
2	-0.113	1	
3	0.385	-0.139	1

Table 8 The correlation matrix for four variables showing the symbol for each correlation

Variable	Variable			
	1	2	3	4
1	1			
2	r_{21}	1		
3	r_{31}	r_{32}	1	
4	r_{41}	r_{42}	r_{43}	1

No Variables in Common. For this version of the test, we will have a correlation matrix involving four variables (Table 8):

Imagine that we are comparing r_{21} with r_{43} .

We need to find the mean of the two correlations that we are comparing ($\bar{r}$).

Next we find a statistic for the two correlations ($\Psi_{12.34}$) from

$$\begin{aligned} \Psi_{12.34} &= 0.5 \times \{[(r_{31} - (\bar{r} \times r_{32})) \times (r_{42} \times (r_{32} \times \bar{r}))] \\ &\quad + [(r_{41} - (r_{31} \times \bar{r})) \times (r_{32} \times (\bar{r} \times r_{31}))] \\ &\quad + [(r_{31} - (r_{41} \times \bar{r})) \times (r_{42} \times (\bar{r} \times r_{41}))] \\ &\quad + [(r_{41} - (\bar{r} \times r_{42})) \times (r_{32} \times (r_{42} \times \bar{r}))]\}. \end{aligned} \quad (88)$$

Next we need the covariance between the two correlations ($\bar{s}_{12.34}$) from

$$\bar{s}_{12.34} = \frac{\Psi_{12.34}}{(1-\bar{r})^2}. \quad (89)$$

We next need to transform the correlations we wish to compare using Fisher's transformation r'_{21} and r'_{43} . We can now put the values into the following equation for a z -test:

$$z = (r'_{21} - r'_{43}) \times \left[\frac{\sqrt{n-3}}{\sqrt{2 - (2 \times \bar{s}_{12.34})}} \right], \quad (90)$$

where n is the sample size

The probability of this z -value can be found from the standard normal distribution.

Example

Twenty people each provide scores on four variables. The correlations between the variables are shown in Table 9:

Comparing r_{21} with r_{43}

Table 9 The correlation matrix of four variables

	1	2	3	4
1	1			
2	-0.113	1		
3	0.385	-0.139	1	
4	0.008	-0.284	-0.111	1

$$\begin{aligned}\bar{r} &= -0.112 \\ \Psi_{12,34} &= -0.110 \\ \bar{s}_{12,34} &= -0.113 \\ r'_{21} &= -0.113 \\ r'_{43} &= -0.112 \\ n &= 20 \\ z &= -0.004\end{aligned}$$

The critical value of z with $\alpha = 0.05$ for a two-tailed test is 1.96.

Decision: fail to reject H_0 .

t Test for Regression Coefficient. This tests the size of an unstandardized regression coefficient (see **Multiple Linear Regression**). In the case of simple regression, where there is only one predictor variable, the null hypothesis is that the regression in the population is 0; that is, that the variance in the predictor variable does not account for any of the variance in the criterion variable. In **multiple linear regression**, the null hypothesis is that the predictor variable does not account for any variance in the criterion variable, which is not accounted for by the other predictor variables.

The version of the t Test is

$$t = \frac{b}{s.e.}, \quad (91)$$

where b is the unstandardized regression coefficient
 $s.e.$ is the standard error for the regression coefficient
In simple regression, the standard error is found from

$$s.e. = \sqrt{\frac{MS_{\text{res}}}{SS_p}}, \quad (92)$$

where MS_{res} is the mean squares of the residual for the regression

SS_p is the sum of squares for the predictor variable.
For multiple regression, the standard error takes into account the interrelationship between the predictor variable for which the $s.e.$ is being calculated and the other predictor variables in the regression (see [3]).

Degrees of freedom

The degrees of freedom for this version of the t Test are based on p (the number of predictor variables) and n (the sample size): $df = n - p - 1$.

Example

In a simple regression ($p = 1$), $b = 1.3$ and the standard error of the regression coefficient is 0.5

$$n = 30$$

$$df = 28$$

$$t_{(28)} = 2.6$$

The critical value for t with $df = 28$, for a two-tailed test with $\alpha = 0.05$ is 2.048.

Decision: reject H_0 .

In multiple regression, it can be argued that a correction to α should be made to allow for multiple testing. This could be achieved by using a Bonferroni adjustment (see **Multiple Comparison Procedures**). Thus, if there were three predictor variables, α would be divided by 3, and the probability for each of the t Tests would have to be 0.0167 or less to be significant.

F Test for a Single R^2 . This is the equivalent of a one-way, between-subjects ANOVA. In this case, the overall variance within the variable to be predicted (the criterion variable, for example, blood pressure) is separated into two sources: that which can be explained by the relationship between the predictor variable(s) (for example, hours of daily exercise, a measure of psychological stress, and daily salt intake) and the criterion variable, and that which cannot be explained by this relationship, the residual.

The equation for this F test is

$$F = \frac{(N - p - 1) \times R^2}{(1 - R^2) \times p}, \quad (93)$$

where N is the sample size

p is the number of predictor variables

R^2 is the squared multiple correlation coefficient

Degrees of freedom

The regression degrees of freedom are p (the number of predictor variables)

The residual degrees of freedom are $N - p - 1$

Example

Number of predictor variables: 3

Sample size: 336

Regression df : 3

Residual df: 332

$$R^2 = 0.03343$$

$$F_{(3,332)} = \frac{(336 - 3 - 1) \times .03343}{(1 - .03343) \times 3} = 3.83$$

Critical F -value with df of 3 and 332 for $\alpha = 0.05$ is 2.63.

Decision: Reject H_0 .

F Test for Comparison of Two R^2 . This tests whether the addition of predictor variables to an existing regression model adds significantly to the amount of variance which the model explains. If only one variable is being added to an existing model, then the information about whether it adds significantly is already supplied by the t Test for the regression coefficient of the newly added variable.

The equation for this F test is

$$F = \frac{(N - p_1 - 1) \times (R_1^2 - R_2^2)}{(p_1 - p_2) \times (1 - R_1^2)}, \quad (94)$$

where N is the sample size.

The subscript 1 refers to the regression with more predictor variables and subscript 2 the regression with fewer predictor variables.

p is the number of predictor variables.

R^2 is the squared multiple correlation coefficient from a regression.

Degrees of freedom

The regression df = $p_1 - p_2$, while the residual df = $N - p_1 - 1$.

Example

$$R_1^2 = 0.047504$$

Number of predictor variables (p_1): 5

$$R_2^2 = 0.03343$$

Number of predictor variables (p_2): 3

Total sample size 336

df for regression = $5 - 3 = 2$

df for residual = $336 - 5 - 1 = 330$

$$F_{(2,330)} = 2.238$$

The critical value of F with df of 2 and 330 for $\alpha = 0.05$ is 3.023.

Decision: Fail to reject H_0 .

Frequencies and Proportions

Chi-square

Chi-square is a distribution against which the results of a number of statistical tests are compared. The two most frequently used tests that use this distribution are themselves called chi-square tests and are used when the data take the form of frequencies. Both types involve the comparison of frequencies that have been found (observed) to fall into particular categories with the frequencies that could be expected if the null hypothesis were correct. The categories have to be mutually exclusive; that is, a case cannot appear in more than one category.

The first type of test involves comparing the frequencies in each category for a single variable, for example, the number of smokers and nonsmokers in a sample. It has two variants, which have a different way of viewing the null hypothesis-testing process. One version is like the example given above, and might have the null hypothesis that the number of smokers in the population is equal to the number of nonsmokers. However, the null hypothesis does not have to be that the frequencies are equal; it could be that they divide the population into particular proportions, for example, 0.4 of the population are smokers and 0.6 are nonsmokers.

The second way in which this test can be used is to test whether a set of data is distributed in a particular way, for example, that they form a normal distribution. Here, the expected proportions in different intervals are derived from the proportions of a normal curve, with the observed mean and standard deviation, that would lie in each interval and H_0 is that the data are normally distributed.

The second most frequent chi-squared test is for **contingency tables** where two variables are involved, for example, the number of smokers and nonsmokers in two different socioeconomic groups.

All the tests described here are calculated in the following way:

$$\chi^2 = \sum \frac{(f_o - f_e)^2}{f_e}, \quad (95)$$

where f_o and f_e are the observed and expected frequencies, respectively.

The degrees of freedom in these tests are based on the number of categories and not on the sample size.

One assumption of this test is over the size of the expected frequencies. When the degrees of freedom are 1, the assumption is that all the expected frequencies will be at least 5. When the df is greater than 1, the assumption is that at least 20% of the expected frequencies will be 5.

Yates [9] devised a correction for chi-square when the degrees of freedom are 1 to allow for the fact that the chi-squared distribution is continuous and yet when $df = 1$, there are so few categories that the chi-squared values from such a test will be far from continuous; hence, the Yates test is referred to as a *correction for continuity*. However, it is considered that this variant on the chi-squared test is only appropriate when the marginal totals are fixed, that is, that they have been chosen in advance [6]. In most uses of chi-squared, this would not be true. If we were looking at gender and smoking status, it would make little sense to set, in advance, how many males and females you were going to sample, as well as how many smokers and nonsmokers.

Chi-square corrected for continuity is found from

$$\chi^2_{(1)} = \sum \frac{(|f_o - f_e| - 0.5)^2}{f_e}, \quad (96)$$

Where $|f_o - f_e|$ means take the absolute value, in other words, if the result is negative, treat it as positive.

One-group Chi-square/Goodness of Fit

Equal Proportions. In this version of the test, the observed frequencies that occur in each category of a single variable are compared with the expected frequencies, which are that the same proportion will occur in each category.

Degrees of freedom

The df are based on the number of categories (k); $df = k - 1$.

Example

A sample of 45 people are placed into three categories, with 25 in category A, 15 in B, and 5 in C. The expected frequencies are calculated by dividing the total sample by the number of categories. Therefore, each category would be expected to have 15 people in it.

$$\chi^2 = 13.33$$

$$df = 2$$

The critical value of the chi-squared distribution with $df = 2$ and $\alpha = 0.05$ is 5.99.

Decision: reject H_0 .

Test of Distribution. This test is another use of the previous test, but the example will show how it is possible to test whether a set of data is distributed according to a particular pattern. The distribution could be uniform, as in the previous example, or nonuniform.

Example

One hundred scores have been obtained with a mean of 1.67 and a standard deviation of 0.51. In order to test whether the distribution of the scores deviates from being normally distributed, the scores can be converted into z -scores by subtracting the mean from each and dividing the result by the standard deviation. The z -scores can be put into ranges. Given the sample size and the need to maintain at least 80% of the expected frequencies at 5 or more, the width of the ranges can be approximately 1/2 a standard deviation except for the two outer ranges, where the expected frequencies get smaller, the further they go from the mean. At the bottom of the range, as the lowest possible score is 0, the equivalent z -score will be -3.27 . At the top end of the range, there is no limit set on the scale.

By referring to standard tables of probabilities for a normal distribution, we can find out what the expected frequency would be within a given range of z -scores. The following table (Table 10) shows the expected and observed frequencies in each range.

$$\chi^2 = 3.56$$

$$df = 8 - 1 = 7$$

Table 10 The expected (under the assumption of normal distribution) and observed frequencies of a sample of 100 values

From z	to z	f_e	f_o
-3.275	-1.500	6.620	9
-1.499	-1.000	9.172	7
-0.999	-0.500	14.964	15
-0.499	0.000	19.111	22
0.001	0.500	19.106	14
0.501	1.000	14.953	15
1.001	1.500	9.161	11
1.501	5.000	6.661	7

The critical value for chi-squared distribution with $df = 7$ at $\alpha = 0.05$ is 14.07.
Decision: Fail to reject H_0 .

Chi-square Contingency Test

This version of the chi-square test investigates the way in which the frequencies in the levels of one variable differ across the other variable. Once again it is for categorical data. An example could be a sample of blind people and a sample of sighted people; both groups are aged over 80 years. Each person is asked whether they go out of their house in a normal day. Therefore, we have the variable visual condition with the levels blind and sighted, and another variable whether the person goes out, with the levels yes and no. The null hypothesis of this test would be that the proportions of sighted and blind people going out would be the same (which is the same as saying that the proportions staying in would be the same in each group). This can be rephrased to say that the two variables are independent of each other: the likelihood of a person going out is not linked to that person's visual condition.

The expected frequencies are based on the marginal probabilities. In this example, that would be the number of blind people, the number of sighted people, the number of the whole sample who go out, and the number of the whole sample who do not go out. Thus, if 25% of the entire sample went out, then the expected frequencies would be based on 25% of each group going out and, therefore, 75% of each not going out.

The degrees of freedom for this version of the test are calculated from the number of rows and columns in the **contingency table**: $df = (r - 1) \times (c - 1)$, where r is the number of rows and c the number of columns in the table.

Example

Two variables A and B each have two levels. Twenty-seven people are in level 1 of variable A and 13 are in level 2 of variable A. Twenty-one people are in level 1 of variable B and 19 are in level 2 (Table 11).

If variables A and B are independent, then the expected frequency for the number who are in the first level of both variables will be based on the fact that 27 out of 40 (or 0.675) were in level 1 of variable A and 21 out of 40 (or 0.525) were in level 1 of variable B. Therefore, the proportion who would be

Table 11 A contingency table showing the cell and marginal frequencies of 40 participants

		Variable A		Total
		1	2	
Variable B	1	12	9	21
	2	15	4	19
Total		27	13	40

expected to be in level 1 of both variables would be $.675 \times .525 = 0.354375$ and the expected frequency would be $0.354375 \times 40 = 14.175$.

$$\chi^2 = 2.16$$

$$df = (2 - 1) \times (2 - 1) = 1$$

The critical value of chi-square with $df = 1$ and $\alpha = 0.05$ is 3.84.

Decision: Fail to reject H_0 .

z-test for Proportions

Comparison between a Sample and a Population Proportion. This test compares the proportion in a sample with that in a population (or that which might be assumed to exist in a population).

The standard error for this test is $\sqrt{\frac{\pi \times (1 - \pi)}{n}}$

where

π is the proportion in the population

n is the sample size

The equation for the z-test is

$$z = \frac{p - \pi}{\sqrt{\frac{\pi \times (1 - \pi)}{n}}}, \quad (97)$$

where p is the proportion in the sample.

Example

In a sample of 25, the proportion to be tested is 0.7 Under the null hypothesis, the proportion in the population is 0.5

$$z = \frac{.7 - .5}{\sqrt{\frac{.5 \times (1 - .5)}{25}}} = 2$$

The critical value for z with $\alpha = 0.05$ for a two-tailed test is 1.96.

Decision: Reject H_0 .

Comparison of Two Independent Samples. Under the null hypothesis that the proportions in the populations from which two samples have been taken are the same, the standard error for this test is

$$\sqrt{\frac{\pi_1 \times (1 - \pi_1)}{n_1} + \frac{\pi_2 \times (1 - \pi_2)}{n_2}}$$

where

π_1 and π_2 are the proportions in each population
 n_1 and n_2 are the sizes of the two samples.

When the population proportion is not known, it is estimated from the sample proportions.

The equation for the z -test is

$$z = \frac{p_1 - p_2}{\sqrt{\frac{p_1 \times (1 - p_1)}{n_1} + \frac{p_2 \times (1 - p_2)}{n_2}}}, \quad (98)$$

where p_1 and p_2 are the proportions in the two samples.

Example

Sample 1: $n = 30$, $p = 0.7$

Sample 2: $n = 25$, $p = 0.6$

$$z = \frac{.7 - .6}{\sqrt{\frac{.7 \times (1 - .7)}{30} + \frac{.6 \times (1 - .6)}{25}}} = 0.776$$

Critical value for z at $\alpha = 0.05$ with a two-tailed test is 1.96.

Decision: Fail to reject H_0 .

Comparison of Two Correlated Samples. The main use for this test is to judge whether there has been change across two occasions when a measure was taken from a sample. For example, researchers might be interested in whether people's attitudes to banning smoking in public places had changed after seeing a video on the dangers of passive smoking compared with attitudes held before seeing the video. A complication with this version of the test is over the estimate of the standard error. A number of versions exist, which produce slightly different results.

Table 12 The frequencies of 84 participants placed in two categories and noted at two different times

		After		
		A	B	Total
Before	A	15	25	40
	B	35	9	44
Total		50	34	84

However, one version will be presented here from Agresti [1]. This will be followed by a simplification, which is found in a commonly used test.

Given a table (Table 12).

This shows that originally 40 people were in category A and 44 in category B, and on a second occasion, this had changed to 50 being in category A and 34 in category B. This test is only interested in the cells where change has occurred: the 25 who were in A originally but changed to B and the 35 who were in B originally but changed to A. By converting each of these to proportions of the entire sample, $25/84 = 0.297619$ and $35/84 = 0.416667$, we have the two proportions we wish to compare. The standard error for the test is

$$\sqrt{\frac{(p_1 + p_2) - (p_1 - p_2)^2}{n}}$$

where n is the total sample size

The equation for the z -test is

$$z = \frac{p_1 - p_2}{\sqrt{\frac{(p_1 + p_2) - (p_1 - p_2)^2}{n}}}. \quad (99)$$

Example

Using the data in the table above,

$p_1 = 0.297619$

$p_2 = 0.416667$

$n = 84$

$$z = \frac{.297619 - .416667}{\sqrt{\frac{(.297619 + .416667) - (.297619 - .416667)^2}{84}}} = -1.304$$

The critical z with $\alpha = 0.05$ for a two-tailed test is -1.96.

Decision: Fail to reject H_0 .

When the z from this version of the test is squared, this produces the Wald test statistic.

A simplified version of the standard error allows another test to be derived from the resulting z -test: McNemar's test of change.

In this version, the equation for the z -test is

$$z = \frac{p_1 - p_2}{\sqrt{\frac{(p_1 + p_2)}{n}}} \quad (100)$$

Example

Once again using the same data as that in the previous example,

$$z = -1.291.$$

If this z -value is squared, then the statistic is McNemar's test of change, which is often presented in a further simplified version of the calculations, which produces the same result [3].

Catalogue of Probability Density Functions

Probability density functions (PDFs) are mathematical formulae that provide information about how the values of random variables are distributed. For a discrete random variable (one taking only particular values within some interval), the formula gives the probability of each value of the variable. For a continuous random variable (one that can take any value within some interval), the formula specifies the probability that the variable falls within a particular range. This is given by the area under the curve defined by the PDF. Here a list of the most commonly encountered PDFs and their most important properties is provided. More comprehensive accounts of density functions can be found in [1, 2].

Probability Density Functions for Discrete Random Variables

Bernoulli

A simple PDF for a random variable, X , that can take only two values, for example, 0 or 1. Tossing a single coin provides a simple example. Explicitly the density is defined as

$$P(X = x_1) = 1 - P(X = x_0) = p, \quad (1)$$

where x_1 and x_0 are the two values that the random variable can take (often labelled as ‘success’ and ‘failure’) and P denotes probability. The single parameter of the Bernoulli density function is the probability of a ‘success,’ p . The expected value of X is p and its variance is $p(1 - p)$.

Binomial

A PDF for a random variable, X , that is the number of ‘successes’ in a series of n independent Bernoulli variables. The number of heads in n tosses of a coin provides a simple practical example. The binomial density function is given by

$$P(X = x) = \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x}, \quad x = 0, 1, 2, \dots, n. \quad (2)$$

The probability of the random variable taking a value in some range of values is found by simply summing the PDF over the required range. The expected value of X is np and its variance is $np(1 - p)$. Some examples of binomial density functions are shown in Figure 1. The binomial is important in assigning probabilities to simple chance events such as the probability of getting three or more sixes in ten throws of a fair die, in the development of simple statistical significance tests such as the sign test (see catalogue of statistical tests) and as the error distribution used in **logistic regression**.

Geometric

The PDF of a random variable X that is the number of ‘failures’ in a series of independent Bernoulli variables before the first ‘success’. An example is provided by the number of tails before the first head, when a coin is tossed a number of times. The density function is given by

$$P(X = x) = p(1 - p)^{x-1}, \quad x = 1, 2, \dots \quad (3)$$

The geometric density function possesses a *lack of memory property*, by which we mean that in a series of Bernoulli variables the probability of the next n trials being ‘failures’ followed immediately by a ‘success’ remains the same geometric PDF regardless of what the previous trials were. The mean of X is $1/p$ and its variance is $(1 - p)/p^2$. Some examples of geometric density functions are shown in Figure 2.

Negative Binomial

The PDF of a random variable X that is the number of ‘failures’ in a series of independent Bernoulli variables before the k th ‘success.’ For example, the number of tails before the 10th head in a series of coin tosses. The density function is given by

$$P(X = x) = \frac{(k+x-1)!}{(x-1)!k!} p^k (1-p)^x, \quad x = 0, 1, 2, \dots \quad (4)$$

The mean of X is $k(1 - p)/p$ and its variance is $k(1 - p)/p^2$. Some examples of the negative

2 Catalogue of Probability Density Functions

Figure 1 Examples of binomial density functions

Figure 2 Examples of geometric density functions

Figure 3 Examples of negative binomial density functions

binomial distribution are given in Figure 3. The density is important in discussions of overdispersion (see **Generalized Linear Models (GLM)**).

Hypergeometric

A PDF associated with *sampling without replacement* from a population of finite size. If the population consists of r elements of one kind and $N-r$ of another, then the hypergeometric is the PDF of the random variable X defined as the number of elements of the first kind when a random sample of n is drawn. The density function is given by

$$P(X = x) = \frac{\frac{r!(N-r)!}{x!(r-x)!(n-x)!(N-r-n+x)!}}{\frac{N!}{n!(N-n)!}}. \quad (5)$$

The mean of X is nr/N and its variance is $(nr/N)(1-r/n)[(N-n)/(N-1)]$. The hypergeometric density function is the basis of Fisher's

exact test used in the analysis of sparse contingency tables (see **Exact Methods for Categorical Data**).

Poisson

A PDF that arises naturally in many instances, particularly as a probability model for the occurrence of rare events, for example, the emission of radioactive particles. In addition, the Poisson density function is the limiting distribution of the binomial when p is small and n is large. The Poisson density function for a random variable X taking integer values from zero to infinity is defined as

$$P(X = x) = \frac{e^{-\lambda} \lambda^x}{x!}, \quad x = 0, 1, 2, \dots, \infty. \quad (6)$$

The single parameter of the Poisson density function, λ , is both the expected value and variance, that is, the mean and variance of a Poisson random variable are equal. Some examples of Poisson density functions are given in Figure 4.

4 Catalogue of Probability Density Functions

Figure 4 Examples of Poisson density functions

Probability Density Functions for Continuous Random Variables

Normal

The PDF, $f(x)$, of a continuous random variable X defined as follows

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{1}{2} \frac{(x - \mu)^2}{\sigma^2}\right], \quad -\infty < x < \infty, \quad (7)$$

where μ and σ^2 are, respectively the mean and variance of X . When the mean is zero and the variance one, the resulting density is labelled as the *standard normal*. The normal density function is bell-shaped as is seen in Figure 5, where a number of normal densities are shown.

In the case of continuous random variables, the probability that the random variable takes a particular value is strictly zero; nonzero probabilities can only be assigned to some range of values of the variable. So, for example, we say that $f(x)dx$ gives the probability of X falling in the very small interval, dx , centered on x , and the probability that X falls

Figure 5 Normal density functions

in some interval, $[A, B]$ say, is given by integrating $f(x)dx$ from A to B .

The normal density function is ubiquitous in statistics. The vast majority of statistical methods are based on the assumption of a normal density for the observed data or for the error terms in models for the data. In part this can be justified by an appeal to the **central limit theorem**. The density function first

appeared in the papers of de Moivre at the beginning of the eighteenth century and some decades later was given by **Gauss** and **Laplace** in the theory of errors and the least squares method. For this reason, the normal is also often referred to as the *Gaussian* or *Gaussian-Laplace*.

Uniform

The mean of such a random variable is having constant probability over an interval. The density function is given by

$$f(x) = \frac{1}{\beta - \alpha}, \quad \alpha < x < \beta. \quad (8)$$

The mean of the density function is $(\alpha + \beta)/2$ and the variance is $(\beta - \alpha)^2/12$. The most commonly encountered version of this density function is one in which the parameters α and β take the values 0 and 1 respectively and is used in generating quasi-random numbers.

Exponential

The PDF of a continuous random variable, X , taking only positive values. The density function is given by

$$f(x) = \lambda e^{-\lambda x}, \quad x > 0. \quad (9)$$

The single parameter of the exponential density function, λ , determines the shape of the density function, as we see in Figure 6, where a number of different exponential density functions are shown. The mean of an exponential variable is $1/\lambda$ and the variance is $1/\lambda^2$.

The exponential density plays an important role in some aspects of **survival analysis** and also gives the distribution of the time intervals between independent consecutive random events such as particles emitted by radioactive material.

Beta

A PDF for a continuous random variable X taking values between zero and one. The density function is defined as

$$f(x) = \frac{\Gamma(p+q)}{\Gamma(p)\Gamma(q)} x^{p-1} (1-x)^{q-1}, \quad 0 < x < 1, \quad (10)$$

Figure 6 Exponential density functions

where $p > 0$ and $q > 0$ are parameters that define particular aspects of the shape of the beta density and Γ is the gamma function (see [3]). The mean of a beta variable is $p/(p+q)$ and the variance is $pq/(p+q)^2(p+q+1)$.

Gamma

A PDF for a random variable X that can take only positive values. The density function is defined as

$$f(x) = \frac{1}{\Gamma(\alpha)} x^{\alpha-1} e^{-x}, \quad x > 0, \quad (11)$$

where the single parameter, α , is both the mean of X and also its variance.

The gamma density function can often act as a useful model for a variable that cannot reasonably be assumed to have a normal density function because of its positive **skewness**.

Chi-Squared

The PDF of the sum of squares of a number (ν) of independent standard normal variables given by

$$f(x) = \frac{1}{2^{\nu/2} \Gamma(\nu/2)} x^{(\nu-2)/2} e^{-x/2}, \quad x > 0, \quad (12)$$

that is, a gamma density with $\alpha = \nu/2$. The parameter ν is usually known as the *degrees of freedom* of the density. This density function arises in many areas of statistics, most commonly as the null distribution of the chi-squared goodness of fit statistic, for example in the analysis of **contingency tables**.

6 Catalogue of Probability Density Functions

Student's T

The PDF of a variable defined as

$$t = \frac{\bar{X} - \mu}{s/\sqrt{n}}, \quad (13)$$

where $\bar{X}$ is the arithmetic mean of n observations from a normal density with mean μ and s is the sample standard deviation. The density function is given by

$$f(t) = \frac{\Gamma\left\{\frac{1}{2}(\nu+1)\right\}}{(\nu\pi)^{1/2}\Gamma\left(\frac{1}{2}\nu\right)} \left(1 + \frac{t^2}{\nu}\right)^{-\frac{1}{2}(\nu+1)}, \quad -\infty < t < \infty, \quad (14)$$

where $\nu = n - 1$. The shape of the density function varies with ν , and as ν gets larger the shape of the t -density function approaches that of a standard normal. This density function is the null distribution of Student's t -statistic used for testing hypotheses about population means (see **Catalogue of Parametric Tests**).

Fisher's F

The PDF of the ratio of two independent random variables each having a chi-squared distribution, divided by their respective degrees of freedom. The form of the density is that of a beta density with $p = \nu_1/2$ and $q = \nu_2/2$, where ν_1 and ν_2 are, respectively, the degrees of freedom of the numerator and denominator chi-squared variables. Fisher's F density is used to assess the equality of variances in, for example, **analysis of variance**.

Multivariate Density Functions

Multivariate density functions play the same role for *vector random variables* as the density functions described earlier play in the univariate situation. Here we shall look at two such density functions, the multinomial and the multivariate normal.

Multinomial

The multinomial PDF is a multivariate generalization of the binomial density function described earlier.

The density function is associated with a vector of random variables $\mathbf{X}' = [X_1, X_2, \dots, X_k]$ which arises from a sequence of n independent and identical trials each of which can result in one of k possible mutually exclusive and collectively exhaustive events, with probabilities $p_1, p_2, \dots, p_k$. The density function is defined as follows:

$$P(X_1 = x_1, X_2 = x_2, \dots, X_k = x_k) = \frac{n!}{x_1!x_2!\dots x_k!} p_1^{x_1} p_2^{x_2} \dots p_k^{x_k}, \quad (15)$$

where x_i is the number of trials with outcome i . The expected value of X_i is np_i and its variance is $np_i(1 - p_i)$. The covariance of X_i and X_j is $-np_i p_j$.

Multivariate Normal

The PDF of a vector of continuous random variables, $\mathbf{X}' = [X_1, X_2, \dots, X_p]$ defined as follows

$$f(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_p) = (2\pi)^{-p/2} |\Sigma| \times \exp\left[-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})' \Sigma^{-1}(\mathbf{x} - \boldsymbol{\mu})\right], \quad (16)$$

where $\boldsymbol{\mu}$ is the mean vector of the variables and Σ is their covariance matrix. The multivariate density function is important in several areas of **multivariate analysis** for example, **multivariate analysis of variance**.

The simplest version of the multivariate normal density function is that for two random variables and known as the *bivariate normal density function*. The density function formula given above now reduces to

$$f(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \exp\left\{-\frac{1}{1-\rho^2} \times \left[\frac{(x_1 - \mu_1)^2}{\sigma_1^2} - 2\rho\frac{(x_1 - \mu_1)(x_2 - \mu_2)}{\sigma_1\sigma_2} + \frac{(x_2 - \mu_2)^2}{\sigma_2^2}\right]\right\}, \quad (17)$$

where $\mu_1, \mu_2, \sigma_1, \sigma_2, \rho$ are, respectively, the means, standard deviations, and correlation of the two variables. Perspective plots of such density functions are shown in Figure 7.

Figure 7 Four bivariate normal density functions with means 5 and standard deviations 1 for variables 1 and 2 and with correlations equal to 0.0, 0.3, 0.6, and 0.9

Catastrophe Theory

Introduction

Catastrophe theory describes how small, continuous changes in control parameters (i.e., independent variables that influence the state of a system) can have sudden, discontinuous effects on dependent variables. Such discontinuous, jumplike changes are called *phase-transitions* or *catastrophes*. Examples include the sudden collapse of a bridge under slowly mounting pressure, and the freezing of water when temperature is gradually decreased. Catastrophe theory was developed and popularized in the early 1970s [27, 35]. After a period of criticism [34] catastrophe theory is now well established and widely applied, for instance, in the field of physics, (e.g., [1, 26]), chemistry (e.g., [32]), biology (e.g., [28, 31]), and in the social sciences (e.g., [14]).

In psychology, catastrophe theory has been applied to multistable perception [24], transitions between Piagetian stages of child development [30], the perception of apparent motion [21], sudden transitions in attitudes [29], and motor learning [19, 33], to name just a few. Before proceeding to describe the statistical method required to fit the most popular catastrophe model – the cusp model – we first outline the core principles of catastrophe theory (for details see [9, 22]).

Catastrophe Theory

A key idea in catastrophe theory is that the system under study is driven toward an equilibrium state. This is best illustrated by imagining the movement of a ball on a curved one-dimensional surface, as in Figure 1. The ball represents the state of the system, whereas gravity represents the driving force.

Figure 1, middle panel, displays three possible equilibria. Two of these states are stable states (i.e., the valleys or minima) – when perturbed, the behavior of the system will remain relatively unaffected. One state is unstable (i.e., a hill or maximum) – only a small perturbation is needed to drive the system toward a different state.

Systems that are driven toward equilibrium values, such as the little ball in Figure 1, may be classified

Figure 1 Smooth changes in a potential function may lead to a sudden jump. $V(x; c)$ is the potential function, and c denotes the set of control variables

according to their configuration of critical points, that is, points at which the first or possibly second derivative equals zero. When the configuration of critical points changes, so does the qualitative behavior of the system. For instance, Figure 1 demonstrates how the local minimum (i.e., a critical point) that contains the little ball suddenly disappears as a result of a gradual change in the surface. As a result of this gradual change, the ball will suddenly move from its old position to a new minimum. These ideas may be quantified by postulating that the state of the system, x , will change over time t according to

$$\frac{dx}{dt} = \frac{-dV(x; c)}{dx}, \quad (1)$$

where $V(x; c)$ is the potential function that incorporates the control variables c that affect the state of the system. $V(x; c)$ yields a scalar for each state x and vector of control variables c . The concept of a potential function is very general, – for instance, a potential function that is quadratic in x will yield the ubiquitous normal distribution. A system whose dynamics obey (1) is said to be a gradient dynamical system. When the right-hand side of (1) equals zero, the system is in equilibrium.

As the behavior of catastrophe models can become extremely complex when the number of behavioral and control parameters is increased, we will focus here on the simplest and most often applied catastrophe model that shows discontinuous behavior: the cusp model. The cusp model consists of one *behavioral* variable and only two *control* variables. This may seem like a small number, especially since there are probably numerous variables that exert some kind

2 Catastrophe Theory

of influence on a real-life system, – however, very few of these are likely to qualitatively affect transitional behavior. As will be apparent soon, two control variables already allow for the prediction of quite intricate transitional behavior. The potential function that goes with the cusp model is $V(x; c) = (-1/4)x^4 + (1/2)bx^2 + ax$, where a and b are the control variables. Figure 2 summarizes the behavior of the cusp model by showing, for all values of the control variables, those values of the behavioral variable for which the system is at equilibrium (note that the Figure 2 variable names refer to the data example that will be discussed later). That is, Figure 2 shows the states for which the derivative of the potential function is zero (i.e., $V'(x; c) = -x^3 + bx + a = 0$). Note that one entire panel from Figure 1 is associated with only one (i.e., a minimum), or three (i.e., two minima and one maximum) points on the cusp surface in Figure 2.

We now discuss some of the defining characteristics of the cusp model in terms of a model for attitudinal change [7, 29, 35]. More specifically, we will measure attitude as regards political preference, ranging from left-wing to right-wing. Two control

Figure 2 The cusp catastrophe model for attitude change. Of the two control variables, ‘information’ is the *normal* variable, and ‘involvement’ is the *splitting* variable. The behavioral variable is ‘attitude’. The lower panel is a projection of the ‘bifurcation’ area onto the control parameter plane. The bifurcation set consists of those values for ‘information’ and ‘involvement’ combined that allow for more than one attitude. See text for details. Adapted from van der Maas et al. (29)

variables that are important for attitudinal change are *involvement* and *information*. The most distinguishing behavior of the cusp model takes places in the foreground of Figure 2, for the highest levels of involvement. Assume that the lower sheet of the cusp surface corresponds to equilibrium states of being left-wing. As ‘information’ (e.g., experience or environmental effects) more and more favors a right-wing view, not much change will be apparent at first, but at some level of information, a sudden jump to the upper, ‘right-wing’ sheet occurs. When subsequent information becomes available that favors the left-wing view, the system eventually jumps back from the upper sheet unto the lower sheet – but note that this jump does not occur at the same position! The system needs additional impetus to change from one state to the other, and this phenomenon is called *hysteresis*.

Figure 2 also shows that a gradual change of political attitude is possible, but only for low levels of involvement (i.e., in the background of the cusp surface). Now assume one’s political attitude starts out at the neutral point in the middle of the cusp surface, and involvement is increased. According to the cusp model, an increase in involvement will lead to polarization, as one has to move either to the upper sheet or to the lower sheet (i.e., *divergence*), because for high levels of involvement, the intermediate position is *inaccessible*. Hysteresis, divergence, and inaccessibility are three of eight *catastrophe flags* [9], that is, qualitative properties of catastrophe models. Consequently, one method of investigation is to look for the catastrophe flags (i.e., catastrophe detection).

A major challenge in the search of an adequate cusp model is the definition of the control variables. In the cusp model, the variable that causes divergence is called the *splitting variable* (i.e., involvement), and the variable that causes hysteresis is called the *normal variable* (i.e., information). When the normal and splitting variable are correctly identified, and the underlying system dynamics are given by catastrophe theory, this often provides surprisingly elegant insights that cannot be obtained from simple linear models. In the following, we will ignore both the creative aspects of defining appropriate control variables and the qualitative testing of the cusp model using catastrophe flags [30]. Instead, we will focus on the problem of statistically fitting a catastrophe model to empirical data.

Fitting the Cusp Catastrophe Model to Data

Several cusp fitting procedures have been proposed, but none is completely satisfactory (for an overview see [12, 29]). The most important obstacle is that the cusp equilibrium surface is cubic in the dependent variable. This means that for control variables located in the bifurcation area (cf. Figure 2, bottom panel), two values of the dependent variable are plausible (i.e., left-wing/lower sheet and right-wing/upper sheet), whereas one value, corresponding to the unstable intermediate state, is definitely not plausible. Thus, it is important to distinguish between minima of the potential function (i.e., stable states) and maxima of the potential function (i.e., unstable states).

Two methods for fitting the cusp catastrophe models, namely *GEMCAT I and II* [17, 20] and Guastello's polynomial regression technique (see **Polynomial Model**) [10, 11] both suffer from the fact that they consider as the starting point for statistical fitting only those values for the derivative of the potential function that equal zero. The equation $dx/dt = -dV(x; c)/dx = -x^3 + bx + a = 0$ is, however, valid both for minima and maxima – hence, neither GEMCAT nor the polynomial regression technique are able to distinguish between stable equilibria (i.e., minima) and unstable equilibria (i.e., maxima). Obviously, the distinction between stable and unstable states is very important when fitting the cusp model, and neglecting this distinction renders the above methods suspect (for a more detailed critique on the GEMCAT and polynomial regression techniques see [2, 29]).

The most principled method for fitting catastrophe models, and the one under discussion here, is the maximum likelihood method developed by Cobb and coworkers [3, 4, 6]. First, Cobb proposed to make catastrophe theory stochastic by adding a Gaussian white noise driving term $dW(t)$ with standard deviation $D(x)$ to the potential function, leading to

$$dx = \frac{-dV(x; c)}{dx} dt + D(x) dW(t). \quad (2)$$

Equation (2) is a stochastic differential equation (SDE), in which the deterministic term on the right-hand side, $-dV(x; c)/dx$, is called the (*instantaneous*) *drift function*, while $D^2(x)$ is called the (*instantaneous*) *diffusion function*, and $W(t)$ is a

Wiener process (i.e., idealized Brownian motion). The function $D^2(x)$ is the infinitesimal variance function and determines the relative influence of the noise process (for details on SDE's see [8, 15]).

Under the assumption of additive noise (i.e., $D(x)$ is a constant and does not depend on x), it can be shown that the modes (i.e., local maxima) of the empirical probability density function (pdf) correspond to stable equilibria, whereas the antimodes of the pdf (i.e., local minima) correspond to unstable equilibria (see e.g., [15], p. 273). More generally, there is a simple one-to-one correspondence between an additive noise SDE and its stationary pdf. Hence, instead of fitting the drift function of the cusp model directly, it can also be determined by fitting the pdf:

$$p(y|\alpha, \beta) = N \exp \left[-\frac{1}{4}y^4 + \frac{1}{2}\beta y^2 + \alpha y \right], \quad (3)$$

where N is a normalizing constant. In (3), the observed dependent variable x has been rescaled by $y = (x - \lambda)/\sigma$, and α and β are linear functions of the two control variables a and b as follows: $\alpha = k_0 + k_1a + k_2b$ and $\beta = l_0 + l_1a + l_2b$. The parameters λ , σ , k_0 , k_1 , k_2 , l_0 , l_1 , and l_2 can be estimated using maximum likelihood procedures (see **Maximum Likelihood Estimation**) [5].

Although the maximum likelihood method of Cobb is the most elegant and statistically satisfactory method for fitting the cusp catastrophe model to date, it is not used often. One reason may be that Cobb's computer program for fitting the cusp model can sometimes behave erratically. This problem was addressed in Hartelman [12, 13], who outlined a more robust and more flexible version of Cobb's original program. The improved program, Cuspfit, uses a more reliable optimization routine, allows the user to constrain parameter values and to employ different sets of starting values, and is able to fit competing models such as the logistic model. Cuspfit is available at <http://users.fmg.uva.nl/hvandermaas>.

We now illustrate Cobb's maximum likelihood procedure with a practical example on sudden transitions in attitudes [29]. The data set used here is taken from Stouffer et al. [25], and has been discussed in relation to the cusp model in Latané and Nowak [18]. US soldiers were asked their opinion about three issues (i.e., postwar conscription, demobilization, and the Women's Army Corps). An individual attitude score was obtained by combining responses on different questions relating to the

same issue, resulting in an attitude score that could vary between 0 (unfavorable) to 6 (favorable). In addition, respondents indicated the intensity of their opinion on a six-point scale. Thus, this data set consists of one behavioral variable (i.e., attitude) and only one control variable (i.e., the splitting variable ‘intensity’).

Figure 3 displays the histograms of attitude scores for each level of intensity separately. The data show that as intensity increases, the attitudes become polarized (i.e., divergence) resulting in a bimodal histogram for the highest intensities. The dotted line shows the fit of the cusp model. The maximum likelihood method as implemented in Cuspfitt allows for easy model comparison. For instance, one popular model selection method is the Bayesian information criterion (BIC; e.g., [23]), defined as $BIC = -2 \log L + k \log n$, where L is the maximum likelihood, k is the number of free parameters, and n is the number of observations. The BIC implements Occam’s razor by quantifying the trade-off between goodness-of-fit and parsimony, models with lower BIC values being preferable.

The cusp model, whose fit is shown in Figure 3, has a BIC value of 1787. The Cuspfitt program is also able to fit competing models to the data. An example of this is the logistic model, which allows for rapid changes in the dependent variable but cannot handle divergence. The BIC for the logistic model was 1970. To get a feeling for how big this difference really is, one may approximate $P(\text{logistic} | \text{data})$, the probability that the logistic model is

Figure 3 Histograms of attitude scores for five intensities of feeling (data from Stouffer et al., 1950). The dotted line indicates the fit of the cusp model. Both the data and the model show that bimodality in attitudes increases with intensity of feeling. Adapted from van der Maas et al. (29)

true and the cusp model is not, given the data, by $\exp\{(-1/2)(BIC_{\text{logistic}})\} / [\exp\{(-1/2)(BIC_{\text{logistic}})\} + \exp\{(-1/2)(BIC_{\text{cusp}})\}]$ (e.g., [23]). This approximation estimates $P(\text{logistic} | \text{data})$ to be about zero – consequently, the complement $P(\text{cusp} | \text{data})$ equals about one.

One problem of the Cobb method remaining to be solved is that the convenient relation between the pdf and the SDE (i.e., modes corresponding to stable states, antimodes corresponding to unstable states) breaks down when the noise is multiplicative, that is, when $D(x)$ in (2) depends on x . Multiplicative noise is often believed to be present in economic and financial systems (e.g., time series of short-term interest rates, [16]). In general, multiplicative noise arises under nonlinear transformations of the dependent variable x . In contrast, deterministic catastrophe theory is invariant under any smooth and revertible transformation of the dependent variable. Thus, Cobb’s stochastic catastrophe theory loses some of the generality of its deterministic counterpart (see [12], for an in-depth discussion of this point).

Summary and Recommendation

Catastrophe theory is a theory of great generality that can provide useful insights as to how behavior may radically change as a result of smoothly varying control variables. We discussed three statistical procedures for fitting one of the most popular catastrophe models, i.e., the cusp model. Two of these procedures, Guastello’s polynomial regression technique and GEMCAT, are suspect because these methods are unable to distinguish between stable and unstable equilibria. The maximum likelihood method developed by Cobb does not have this problem. The one remaining problem with the method of Cobb is that it is not robust to nonlinear transformations of the dependent variable. Future work, along the lines of Hartelman [12], will have to find a solution to this challenging problem.

Categorizing Data

Categorizing Continuous Variables

Changing a continuous variable to a categorical form is common in many data analyses because of the impression that categorization makes it easier for clinical interpretation and avoids complex statistical assumptions. Indeed, methods of analysis begin with the most basic form of data, a **2 × 2 contingency table**, which classifies data into one of four unique categories. By splitting a continuous variable such as blood pressure, tumor size, or age into two discrete groups (above and below a given threshold, which may be either predetermined or data-dependent), the data can be presented as the number belonging to each classification (above and below).

Another common form of categorical data is ordered categories (i.e., worse, unchanged, improved). Ordered categorical variables are intermediate between continuous variables and binary variables, and can be the result of categorizing (into more than two categories) a continuous variable. Alternatively, the categories may be defined without reference to any continuous variable. Either way, an ordered categorical variable can be further categorized into another ordered categorical variable with fewer categories, or, in the extreme scenario, into a binary variable. Categorization is thus seen to apply to continuous variables, which may be transformed into ordered categorical variables or to binary variables, and to ordered categorical variables, which may be transformed into ordered categorical variables with fewer categories or to binary variables.

Categorization is attractive for descriptive purposes and for separating patients into risk groups. It also provides a data structure conducive to a familiar, simply executed, and easily interpreted analysis. Given two groups, and data from each group classified into the same two groups (above or below the same threshold), one can produce confidence intervals for the difference between proportions or test the equality, across the groups, of the two success probabilities (e.g., statistical independence between groups and outcomes). However, the advantages and disadvantages need to be understood prior to engaging in this approach.

Methods of Categorization

To categorize a continuous variable or an ordered categorical variable, one needs to determine a cutpoint. This determination may be made based on prior knowledge, or the data at hand. If the data at hand are used, then the determination of the cutpoint may be based on a visual inspection of a graph, the optimization of prediction of or association with some other variable, the maximization of a between-group difference, or the minimization of a *P* value. If the data are to be used to select the cutpoint, then a graphical display may give insight into the appropriate grouping. Inspection of data from the sample using plots can reveal clusters within any given variable and relationships between two variables (i.e., outcome and prognostic variables). These can help to identify potential cutpoints that differentiate patients into distinct groups (i.e., high and low risk). So, for example, if in a given sample of subjects the ages could range from 18 to 80, but as it turns out there is no middle (each subject is either under 30 or over 70), then there is no need to determine the cutpoint beyond specifying that it might fall between 30 and 70.

Relationships between two variables can appear as step-functions, which may be either monotonic or nonmonotonic (i.e., a U-shaped distribution). In such a case, the effect of the independent variable on the dependent variable depends on which cluster the independent variable falls in. Suppose, for example, that systolic blood pressure depends on age, but not in a continuous fashion. That is, suppose that the mean blood pressure for the patients born in a given decade is the same, independent of which year within the decade they were born. If this were the case, then it would provide a clear idea of where the cutpoints should be placed.

Another approach is to choose equally spaced intervals or, if this creates sparsely populated groups, then the median value can be used to obtain roughly equally represented groups [8]. A more systematic approach is to use various cutpoints to determine the one that best differentiates risk groups [11]. Of course, the *P* value that results from a naïve comparison using this optimally chosen cutpoint will be artificially low [3], however, and even if it is adjusted to make it valid, the estimate remains biased [9]. Mazumdar and Glassman [10] offer a nice summary on choosing cutpoints, which includes

a description of the P value adjustment formulae, while Altman [1] discusses creating groups in a regression setting.

Standard cutpoints, which are not influenced by the present data, are useful particularly when comparing results across studies because if the cutpoint changes over time, then it is difficult, if not impossible, to use past information for comparing studies or combining data. In fact, definitions of severity of cancer, or any other disease, that vary over time can lead to the illusion that progress has been made in controlling this disease when in fact it may not have – this is known as *stage migration* [7].

Implications of Chosen Cutpoints

It is illustrated in the literature that categorizing continuous outcome variables can lead to a loss of information, increased chance of misclassification error, and a loss in statistical **power** [1, 8, 12–17]. Categorizing a continuous predictor variable can lead to a reversal in the direction of its effect on an outcome variable [5]. Ragland [13] illustrates with a blood pressure example that the choice of cutpoint affects the estimated measures of association (i.e., proportion differences, prevalence ratios, and odds ratios) and that as the difference between the two distribution means increases, the variations in association measurements and power increase. In addition, Connor [6] and Suissa [18] show that tests based on frequencies of a dichotomous endpoint are, in general, less efficient than tests using mean-value statistics when the underlying distribution is normal (efficiency is defined as the ratio of the expected variances under each model; the model with the lower variance ratio is regarded as more efficient).

Even if the categorization is increased to three or four groups, the relative efficiency (see **Asymptotic Relative Efficiency**) is still less than 90%. This implies that if there really is a difference to detect, then a study using categorized endpoints would require a larger sample size to be able to detect it than would a study based on a continuous endpoint. Because of this, it has recently been suggested that binary variables be ‘reverse dichotomized’ and put together to form the so-called information-preserving composite endpoints, which are more informative than any of the binary endpoints used in their creation (see **Analysis of Covariance: Nonparametric**) [2].

These more informative endpoints are then amenable to a wider range of more powerful analyses that make use of all the categories, as opposed to just Fisher’s exact test on two collapsed categories. More powerful analyses include the **Wilcoxon-Mann Whitney test** and the Smirnov test (see **Kolmogorov-Smirnov Tests**), as well as more recently developed tests such as the convex hull test [4] and adaptive tests [3].

So why would one consider categorizing a continuous variable if it increases the chance of missing real differences, increases the chance of misclassification, and increases the sample size required to detect differences? The best argument thus far seems to be that categorization simplifies the analyses and offers a better approach to understanding and interpreting meaningful results (proportions versus mean-values). Yet one could argue that when planning a research study, one should select the primary response variable that will give the best precision of an estimate or the highest statistical power. In the same respect, prognostic variables (i.e., age, tumor size) should be categorized only according to appropriate methodology to avoid misclassification. Because it is common to group populations into risk groups for analysis and for the purposes of fulfilling eligibility criteria for stratified randomization schemes, categorization methods need to be available.

The best approach may be to collect data on a continuum and then categorize when necessary (i.e., for descriptive purposes). This approach offers the flexibility to conduct the prespecified analyses whether they are based on categorical or continuous data, but it also allows for secondary exploratory and sensitivity analyses to be conducted.

Cattell, Raymond Bernard

Born: March 20, 1905, in West Bromwich, UK.

Died: February 2, 1998, in Honolulu, USA.

At the age of just 19 years, Raymond Bernard Cattell was awarded his first university degree (with first class honors) from University College, London in 1924, reading chemistry. However, during his time here, he was influenced by the thinking and research of three of the most significant figures in mathematical and statistical psychology in the twentieth century, **Cyril Burt**, **Ronald Fisher**, and **Charles Spearman**; all of whom were working within laboratories in close proximity to his own. The magnificent intellectual stimulation of these three, allied to Cattell's own interest in the classification process (exemplified in Dmitri Mendeléeff's Periodic Table of elements as a model for classifying human attributes), led him to pursue a doctorate in human psychology in King's College, London, working on cognition and perception. Spearman was his mentor throughout this period, and in 1929, he was awarded his Ph.D. During the next eight years, owing to the lack of any research positions in the new discipline of psychology, he took a teaching position at Exeter University, UK, within the Education and Psychology department. In 1932, he became Director of the School Psychological Services and Clinic in Leicester, UK. However, Cattell's research career really began in earnest in 1937 with an invitation to join Edward Thorndike in a research associate position within his laboratory at Columbia University, USA. From here, he accepted the G. Stanley Hall professorship at Clark University in Massachusetts, where he developed and announced his theory of fluid versus crystallized intelligence to the 1941 American Psychological Association convention. From 1941 to 1944, he worked within the Harvard University psychology faculty. It was during this time at Harvard that the factor analytic and multivariate psychometrics that was to be his major contribution to human psychology began. In 1945, he was appointed to a newly created research professorship in psychology at the University of Illinois, USA. He remained at Illinois for the next 29 years in the Laboratory of Personality and Group Analysis until his 'official'

retirement in 1973. In 1949, he published the first version of what was to become one of the world's most famous personality tests, the Sixteen Personality Factor test. After his retirement in 1973, Cattell set up the Institute for Research on Morality and Adjustment in Boulder, Colorado, USA. Then, after an existing heart condition was aggravated by the cold mountain conditions and high altitude of his location in Boulder, he moved to Hawaii in 1978 as an unpaid visiting professor within the department of psychology, a position which he held for 20 years until his death. In 1997, one year before his death, he was nominated to receive the prestigious gold medal award for lifetime achievement from the American Psychological Association and the American Psychological Foundation. Unfortunately, owing to an ongoing controversy about his later work, which publicly distorted his actual research and thinking on morality and sociological matters, he declined to accept the award.

Raymond Cattell authored and coauthored 55 books and over 500 scientific articles. Some of these are the most significant publications in human trait psychology and psychometrics of that era. For example, his 1957 book entitled *Personality and Motivation Structure and Measurement* [1] was the handbook from which the major tenets and research outputs of Cattellian Theory were first exposed in a detailed and unified fashion. In 1966, the *Handbook of Multivariate Experimental Psychology* [2] was published, a landmark publication that described research and advances in multivariate statistics, ability, motivation, and personality researches. Another influential book was authored by him in 1971, *Abilities, Their Structure, Growth, and Action* [3]. This book described the entire theory of Fluid and Crystallized Intelligence, along with introducing the hierarchical multivariate model of human abilities that now dominates modern-day psychometric theories of intelligence. His 1978 book on **factor analysis** [4] formed the major summary of his innovations and approach to using this multivariate methodology.

Censored Observations

Most common statistical analyses are based on actually observing the values of the observations to be analyzed. However, it is not always the case that an observation is observed in its entirety. Three common types of censoring are right censoring, left censoring, and interval censoring. Each arises in different contexts. An observation can be left censored, for example, if a study is conducted to measure how long it takes for infants to develop a certain skill, but some infants have already acquired the skill by the time they are studied. In such a case, the time to develop this skill is not observed for this infant, but it is known that this time is shorter than the infant's age. So the actual time, though unknown, is known to fall within an interval from zero to the observation time, or everything to the left of the observation time.

Another context in which an observation may be left censored is when an assay has a certain detection limit. That is, a certain agent will be detected only if its concentration exceeds the detection limit. If it is not detected, then this does not mean that it is not present. Rather, it means that the concentration falls between zero and the detection limit, or left of the detection limit. So it is left censored.

Similarly, if all that is known is that an agent was detected but its concentration is not known, then the unobserved concentration is known only to fall to the right of the detection limit, so it is right censored [7]. Right censoring is sufficiently common that it has been further classified into Type I and Type II censoring. Type I censoring describes the situation in which a study is terminated at a particular point in time, even if not all patients have been observed to the event of interest. In this case, the censoring time is fixed (unless some patients dropped out of the trial prior to this common censoring time), and the number of events is a random variable. With Type II censoring, the study would be continued until a fixed number of events are observed. For example, the trial may be stopped after exactly 50 patients die. In this case, the number of events is fixed, and censoring time is the random variable.

In most **clinical trials**, patients could be censored owing to reasons not under the control of the

investigator. For example, some patients may be censored because of loss to follow-up, while others are censored because the study has terminated. This censoring is called *random censoring*.

Besides left and right censoring, there is also interval censoring, in which an observation is known only to fall within a certain interval. If, for example, a subject is followed for the development of cancer, and does not have cancer for the first few evaluations, but then is found to have cancer, then it is known only that the cancer developed (at least to the point of being detectable) between the last 'clean' visit and the first visit during which the cancer was actually detected. Technically speaking, every observation is interval censored, because of the fact that data are recorded to only a finite number of decimal places. An age of 56 years, for example, does not mean that the subject was born precisely 56 years ago, to the second. Rather, it generally means that the true age is somewhere between 55.5 and 56.5 years. Of course, when data are recorded with enough decimal places to make them sufficiently precise, this distinction is unimportant, and so the term interval censoring is generally reserved for cases in which the interval is large enough to be of some concern. That is, the lower endpoint and the upper endpoint might lead to different conclusions.

One other example of interval censoring is for the P value of an exact permutation test (*see Permutation Based Inference*) whose reference distribution is discrete. Consider, for example, Fisher's exact test (*see Exact Methods for Categorical Data*). Only certain P values can be attained because of the discrete distribution (even under the null hypothesis, the P value is not uniformly distributed on the unit interval), and so what is interval censored is the value the P value would have attained without the conservatism. For truth in reporting, it has been suggested that this entire interval be reported as the P value interval [1] (*see Mid- P Values*).

Of course, left censoring, right censoring, and interval censoring do not jointly cover all possibilities. For example, an observation may be known only to fall outside of an interval, or to fall within one of several intervals. However, left censoring, right censoring, and interval censoring tend to cover most of the usual applications.

The analysis of censored data, regardless of the type of censoring, is not as straightforward as the analysis of completely observed data, and special methods have been developed. With censoring, the endpoint may be considered to be measured on only a partially ordered scale, and so methods appropriate for partially ordered endpoints may be used [2]. However, it is more common to use the log-rank test to test if two distributions are the same, Cox proportional hazards regression [3, 4] to assess covariate effects, and Kaplan–Meier curves [5] to estimate the survival time distribution (*see Survival Analysis*). Accelerated failure time methods can also be used. See also [6]. It has been noted that when analyzing censored data, a commonsense criterion called ‘rationality’ may conflict with the desirable property of unbiasedness of a test [8].

Although the concept of censoring may have developed in the biomedical research, censored observations may occur in a number of different areas of research. For example, in the social sciences one may study the ‘survival’ of a marriage. By the end of the study period, some subjects probably may still be married (to the same partner), and hence those subjects represent censored observations. Likewise, in engineering, components have failure times, which may be right censored.

Census

Definition

In a broad sense, a census can be defined as the gathering of information from all members of any type of population. In this broad sense, the term has, for example, been used to refer to an enumeration of the mountain gorilla population in the vicinity of the Virunga Volcanoes in Central Africa, which established a 17% growth in the population between 1989 and 2004.

In the context of behavioral research, however, the more particular definition issued by the United Nations is used. According to the latter definition, a census can be described as ‘the total process of collecting, compiling, evaluating, analyzing and publishing demographic, economic and social data pertaining, at a specified time, to all persons in a country or in a well-delimited part of a country’ [6]. The latter definition highlights several key features of a census [1, 3]:

1. Government sponsorship: A census is sponsored by the government of the country or area in which the census takes place, because only a government can provide the required resources for the census and the necessary authority and legislation to make public participation to the census enforceable.
2. The census must cover a precisely defined area. Most often, country boundaries define the census area.
3. All persons in the scope of the census are included without omission or duplication.
4. The information is collected at the individual level rather than at some aggregate level, for example, household level. Note, however, that this does not preclude the collection of information about the household to which the individual belongs.
5. The information must be gathered within a specified time interval.
6. The information that is collected via the census must be made publicly available.

Purpose of the Census

Earlier on, we have mentioned that censuses are sponsored by the government, because only a

government can establish the necessary conditions for its conduct. Government involvement is, however, also due to the fact that the information collected by the census is necessary and sometimes vital for government policy and administration. For instance, the main objective of the US census is to perform an enumeration of the total population residing on its territory, allowing the proportional apportionment of federal funds and seats in the US House of Representatives to the different states [7]. Similarly, the South African census provides data to guide the postapartheid Reconstruction and Development Program (RDP). This census is used for the distribution of resources to redress social inequalities by providing expanded opportunities for education, housing, employment, and improving the situation of women and the youth. Additionally, the South African census provides data on fertility, mortality, and the devastation resulting from the HIV/AIDS pandemic [2].

These purposes, of course, also have their impact on the content of the census. Often, the content of the census depends on the country’s needs at the time that the census is administered although some standard information is collected in nearly every census. The United Nations [5] have also approved a set of recommendations for population censuses that includes the following topics: location at time of census, place of usual residence, relation to the head of the household or family, sex, age, marital status, place of birth, citizenship, whether economically active or not, occupation, industry, status (e.g., employer, employee), language, ethnic characteristics, literacy, education, school attendance, and number of children.

A Historical Perspective

Population counts go back a long time in history. There are reports of population counts in ancient Japan, by ancient Egyptians, Greeks, Hebrews, Romans, Persians, and Peruvians [3, 4]. The purpose of these surveys was to determine, for example, the number of men at military age or the number of households eligible for taxes. Because of these goals, early censuses did not always focus on the entire population within a country or area. Modern-day censuses are traced back to the fifteenth and sixteenth century. However, the oldest census that has been

carried out on a regular basis is the US census, which was first held in 1790 and henceforth repeated every ten years. The United Kingdom census also has a long tradition, dating back to 1801 and being held every 10 years from then on (except in 1941). By 1983, virtually every country in the world had taken a census of its population [4].

Some countries, like the United States and the United Kingdom, have a tradition of conducting a census every 5 or 10 years. A lot of countries, however, only hold a census when it is necessary and not at fixed dates.

Methodological Issues

The census data are usually gathered in one of two ways: either by self-enumeration or by direct enumeration. In the former case, the questionnaire is given to the individual from whom one wants to collect information and he/she fills out the questionnaire him/herself. In the case of direct enumeration, the questionnaire is filled out via a face-to-face interview with the individual.

Given the fact that the census data are collected via questionnaires, all methodological issues that arise with respect to the construction and the use of questionnaires also apply in the census context (*see Survey Questionnaire Design*). First of all, it is important that the questions are worded in such a way that they are easily understandable for everyone. For this reason, a pilot study is often administered to a limited sample of individuals to test the questionnaire and detect and solve difficulties with the questions as well as with the questionnaire in general (e.g., too long, inadequate layout, etc.). Secondly, individuals might not always provide correct and/or truthful answers to the questions asked. In the context of a census, this problem is, however, somewhat different than in the context of other questionnaire-based research that is not sponsored by the government. On the one hand, the government usually issues legislations that enforce people to provide correct and truthful answers, which might lead some people to do so more than in any other context. On the other hand, because the information is used for government purposes, some people might be hesitant to convey certain information out of fear that it in some way will be used against them.

Thirdly, in the case of direct enumeration, interviewers are used to gather the census information.

It is well known that interviewers often influence respondents' answers to questions. To minimize this type of interviewer effects, it is important to provide these interviewers with the necessary training with respect to good interview conduct. Furthermore, interviewers also need to be supervised in order to avoid fraud.

Another issue that needs to be considered is non-response (*see Missing Data*). Although governments issue legislation that enforces participation in the census, there are always individuals who can or will not cooperate. Usually, these nonresponders do not represent a random sample from the population, but are systematically different from the responders. Hence, there will be some bias in the statistics that are calculated on the basis of the census. However, given the fact that information about some background characteristics of these nonresponders are usually available from other administrative sources, it can be assessed to what extent they are different from the responders and (to some extent) a correction of the statistics is possible.

Over the course of the years, censuses have become more than population enumerations. The US Census, for example, has come to collect much more information, such as data on manufacturing, agriculture, housing, religious bodies, employment, internal migration, and so on [7]. The contemporary South Africa [2] census (*see above*) also illustrates the wide scope of modern censuses. Expanding the scope of a census could not have happened without evolutions in other domains. Use of computers and optical sensing devices for data input have greatly increased the speed with which returned census forms can be processed and analyzed (*see Computer-Adaptive Testing*). Also, censuses have come to use sampling techniques (*see Survey Sampling Procedures*). First of all, certain questions are sometimes only administered to a random sample of the population to avoid high respondent burden due to long questionnaires. This implies that not all questions are administered to all individuals. Questions could for instance be asked on a cyclical basis: One set of questions for individual 1, another set for individual 2, and so on, until individual 6, who again receives the set of questions from the first cycle [7]. As another example, the 2000 US census used a short and a long form, the latter being administered to a random sample of the population.

Secondly, some countries have recently abandoned the idea of gathering information from the entire population, because a lot of administrative information about a country's population has become available via other databases that have been set up over the years. Belgium, for example, from 2001 onward has replaced the former decennial population censuses by a so-called General Socio-economic Survey that collects data on a large sample (Sample fraction: 20–25%) from the population.

Centering in Linear Multilevel Models

Consider the situation in which we have m groups of individuals, where group j has n_j members. We consider a general multilevel model, (see **Linear Multilevel Models**) that is, a random coefficient model for each group of the form

$$y_{ij} = \beta_{0j} + \sum_{s=1}^p x_{ijs} \beta_{sj} + \epsilon_{ij}, \quad (1)$$

where the coefficients are the outcomes of a second regression model

$$\beta_{sj} = \gamma_{0s} + \sum_{r=1}^q z_{jr} \gamma_{rs} + \delta_{sj}. \quad (2)$$

Both the $n_j \times (p+1)$ matrices X_j of first-level predictors and the $p \times (q+1)$ matrix Z of second-level predictors have a leading column with all elements equal to +1, corresponding with the intercepts of the regression equations. To single out the intercepts in our formulas, our indices for both first- and second-level predictors start at zero. Thus, $0 \leq s \leq p$ and $0 \leq r \leq q$ and $x_{ij0} = z_{j0} = 1$ for all i and j . Observe that the predictors X_j and Z are both non-random, either because they are fixed by design or because we condition our model on their observed values.

The disturbance vectors ϵ_j and δ_j have zero expectations. They are uncorrelated with each other and have covariance matrices $V(\epsilon_j) = \sigma^2 I$, where I is the $n_j \times n_j$ identity matrix, and where $V(\delta_j) = \Omega$. The $p \times p$ matrix Ω has elements ω_{st} . It follows that the expectations are

$$\begin{aligned} E(y_{ij}) &= \gamma_{00} + \sum_{r=1}^q z_{jr} \gamma_{r0} + \sum_{s=1}^p x_{ijs} \gamma_{0s} \\ &+ \sum_{s=1}^p \sum_{r=1}^q x_{ijs} z_{jr} \gamma_{rs}, \end{aligned} \quad (3)$$

and the covariances are

$$C(y_{ij}, y_{kj}) = \omega_{00} + \sum_{s=1}^p (x_{ijs} + x_{kjs}) \omega_{0s}$$

$$+ \sum_{s=1}^p \sum_{t=1}^p x_{ijs} x_{kjt} \omega_{st} + \delta^{ik} \sigma^2. \quad (4)$$

Here δ^{ik} is Kronecker's delta, that is, it is equal to one if $i = k$ and equal to zero otherwise. Typically, we define more restrictive models for the same data by requiring that some of the regression coefficients γ_{rs} and some of the variance and covariance components ω_{st} are zero.

In multilevel analysis, the scaling and centering of the predictors is often arbitrary. Also, there are sometimes theoretical reasons to choose a particular form of centering. See Raudenbush and Bryk 2, p. 31–34 or Kreft et al. [1]. In this entry, we consider the effect on the model of translations. Suppose we replace x_{is} by $\tilde{x}_{ijs} = x_{ijs} - a_s$. Thus, we subtract a constant from each first-level predictor, and we use the same constant for all groups. If the a_s are the predictor means, this means *grand mean centering* of all predictor variables. Using grand mean centering has some familiar interpretational advantages. It allows us to interpret the intercept, for instance, as the expected value if all predictors are equal to their mean value. If we do not center, the intercept is the expected value if all predictors are zero, and for many predictors used in behavioral science zero is an arbitrary or impossible value (think of a zero IQ, a zero income, or a person of zero height).

After some algebra, we see that

$$\begin{aligned} \gamma_{00} &+ \sum_{r=1}^q z_{jr} \gamma_{r0} + \sum_{s=1}^p x_{ijs} \gamma_{0s} \\ &+ \sum_{s=1}^p \sum_{r=1}^q x_{ijs} z_{jr} \gamma_{rs} = \tilde{\gamma}_{00} + \sum_{r=1}^q z_{jr} \tilde{\gamma}_{r0} \\ &+ \sum_{s=1}^p \tilde{x}_{ijs} \gamma_{0s} + \sum_{s=1}^p \sum_{r=1}^q \tilde{x}_{ijs} z_{jr} \gamma_{rs}, \end{aligned} \quad (5)$$

with

$$\tilde{\gamma}_{r0} = \gamma_{r0} + \sum_{s=1}^p \gamma_{rs} a_s \quad (6)$$

for all $0 \leq r \leq q$. Thus, the translation of the predictor can be compensated by a linear transformation of the regression coefficients, and any vector of expected values generated by the untranslated model can also be generated by the translated model. This

2 Centering in Linear Multilevel Models

is a useful type of invariance. But it is important to observe that if we restrict our untranslated model, for instance, by requiring one or more γ_{r0} to be zero, then those same γ_{r0} will no longer be zero in the corresponding translated model. We have invariance of the expected values under translation if the regression coefficients of the group-level predictors are nonzero.

In the same way, we can see that

$$\begin{aligned} \omega_{00} + \sum_{s=1}^p (x_{ijs} + x_{kjs})\omega_{0s} \\ + \sum_{s=1}^p \sum_{t=1}^p x_{ijs}x_{kjt}\omega_{st} = \\ \tilde{\omega}_{00} + \sum_{s=1}^p (\tilde{x}_{ijs} + \tilde{x}_{kjs})\tilde{\omega}_{0s} \\ + \sum_{s=1}^p \sum_{t=1}^p \tilde{x}_{ijs}\tilde{x}_{kjt}\tilde{\omega}_{st} \end{aligned} \quad (7)$$

if

$$\begin{aligned} \tilde{\omega}_{00} &= \omega_{00} + 2 \sum_{s=1}^p \omega_{0s}a_s + \sum_{s=1}^p \sum_{t=1}^p \omega_{st}a_sa_t, \\ \tilde{\omega}_{0s} &= \omega_{0s} + \sum_{t=1}^p \omega_{st}a_t. \end{aligned} \quad (8)$$

Thus, we have invariance under translation of the variance and covariance components as well, but, again, only if we do not require the ω_{0s} , that is, the covariances of the slopes and the intercepts, to be zero. If we center by using the grand mean of the predictors, we still fit the same model, at least in the case in which we do not restrict the γ_{r0} or the ω_{s0} to be zero.

If we translate by $\tilde{x}_{ijs} = x_{ijs} - a_{js}$ and thus subtract a different constant for each group, the situation

becomes more complicated. If the a_{js} are the group means of the predictors, this is *within-group centering*. The relevant formulas are derived in [1], and we will not repeat them here. The conclusion is that separate translations for each group cannot be compensated for by adjusting the regression coefficients and the variance components. In this case, there is no invariance, and we are fitting a truly different model. In other words, choosing between a translated and a nontranslated model becomes a matter of either theoretical or statistical (goodness-of-fit) considerations.

From the theoretical point of view, consider the difference in meaning of a grand mean centered and a within-group mean centered version of a predictor such as grade point average. If two students have the same grade point average (GPA), they will also have the same grand mean centered GPA. But GPA in deviations from the school mean defines a different variable, in which students with high GPAs in good schools have the same corrected GPAs as students with low GPAs in bad schools. In the first case, the variable measures GPA; in the second case, it measures how good the student is in comparison to all students in his or her school. The two GPA variables are certainly not monotonic with each other, and if the within-school variation is small, they will be almost uncorrelated.

Central Limit Theory

Description

The normal distribution (*see Catalogue of Probability Density Functions*) is an essential and ubiquitous part of statistics, and many tests make an assumption relating to the normal distribution. The reason that the normal distribution is so omnipresent is because of *the central limit theorem*; it has been described, for example, as ‘the reason **analysis of variance** ‘works’ [3].

The assumption of normality of distribution made by many statistical tests is one that confuses many students – we do not (usually) make an assumption about the distribution of the measurements that we have taken, rather we make an assumption about the sampling distribution of those measurements – it is this sampling distribution that we assume to be normal, and this is where the central limit theorem comes in. The theorem says that the **sampling distribution** of sample means will approach normality as the sample size increases, *whatever the shape of the distribution of the measure that we have taken* (we must warn that the measurements must be independent, and identically distributed [i.i.d.]).

The theorem also tells us that given the population mean μ and variance σ^2 , the mean of the sampling distribution (that is, the mean of all of the means) $\mu_{\bar{x}}$ will be equal to the μ (the population mean), and that the variance of the sample means $\sigma_{\bar{x}}^2$ will be equal to σ^2/n (where n is the size of each of the samples). Taking the square root of this equation gives the familiar formula for the standard deviation of the sampling distribution of the mean, or standard error:

$$se_{\bar{x}} = \sigma_{\bar{x}} = \frac{\sigma}{\sqrt{n}}. \quad (1)$$

The mathematical proof of this requires some mathematical sophistication (although less than many mathematical proofs). One can show the moment-generating function (*see Moments*) of a standardized sample mean asymptotes to the moment-generating function of a standard normal distribution as the sample size increases; [2] it can also be seen at http://en.wikipedia.org/wiki/Central_limit_theorem, or <http://mathworld.wolfram.com/CentralLimitTheorem.html>

Demonstration

The idea of the sampling distribution becoming normal at large samples is one that can be difficult to understand (or believe), but a simple demonstration can show that this can occur. Imagine that our measurement is that of dice rolls – purely random numbers, from 1 to 6. If we were to take a sample of size $N = 1$ roll of a die, record the result, and repeat the procedure, a very large number of times, it is clear that the shape of the distribution would be uniform, not normal – we would find an equal proportion of every value.

It is hardly necessary to draw the graph, but we will do it anyway – it is shown in Figure 1.

The mean of this distribution is equal to 3.5, and the mean value that would be calculated from a dice roll is also equal to 3.5.

If we increase the sample to $n = 2$ dice rolled, the distribution will change shape. A mean roll of 1 can be achieved in only 1 way – to roll a 1 on both dice, therefore the probability of a mean of 1 is equal to $1/(6 \times 6) = 0.028$. A mean of 1.5 can be achieved in two ways: a 1 on the first die, followed by a 2 on the second die, or a 2 on the first die, followed by a 1 on the second die, given a probability of 0.056. We could continue with this for every possible mean score. If we were to do this, we would find the distribution shown in Figure 2. This graph is still not showing a normal distribution, but it is considerably closer to the normal distribution than Figure 1.

If I repeat the operation, with a sample size of 7, we can again calculate the probability of any value arising. For example, to achieve a mean score of 1, you would need to roll a 1 on all 7 dice. The probability of this occurring is equal to $1/6^7 = 0.0000036$ (around 1 in 280 000). In a similar way, we can plot the distribution of the measure – this is shown in Figure 3, along with a normal distribution curve with the same mean and standard deviation. It can be seen that the two curves are very close to each other (although they are not identical).

This demonstration has shown that the sampling distribution can indeed approach the normal distribution as the sample size increases, even though the distribution of the variable is not normal – it is uniform, and the sample size was only 7.

However, this variable was symmetrically distributed and that is not always going to be the case.

2 Central Limit Theory

Figure 1 Probability distribution from samples of $N = 1$

Figure 2 Probability distribution from samples of $N = 2$

Figure 3 Distribution of mean score of 7 dice rolls (bars) and normal distribution with same mean and SD (line)

Imagine that we have a die, which has the original numbers removed, and the numbers 1, 1, 1, 2, 2, 3, added to it. The distribution of this measure in the sample is going to be markedly (positively) skewed, as is shown in Figure 4.

We might ask whether, in these circumstances, the central limit theorem still holds – we can see if the sampling distribution of the mean is normal. For one die, the distribution is markedly skewed, as we have seen. We can calculate the probability of different

Figure 4 Distribution of die rolls, when die is marked 1, 1, 1, 2, 2, 3, $N = 1$

Figure 5 Sampling distribution of dice labelled 1, 1, 1, 2, 2, 3, when $N = 2$

values occurring in larger samples. When $N = 2$, a mean score of 1 can be achieved by rolling a 1 on both die. The probability of this event occurring = $0.5 \times 0.5 = 0.25$. We could continue to calculate the probability of each possible value occurring – these are shown in graphical form in Figure 5. Although we would not describe this distribution as normal, it is closer to a normal distribution than that shown in Figure 4.

Again, if we increase the sample size to 7 (still a very small sample), the distribution becomes a much better approximation to a normal distribution. This is shown in Figure 6.

When the Central Limit Theorem Goes Bad

As long as the sample is sufficiently large, it seems that we can rely on the central limit theorem to ensure

that the sampling distribution of the mean is normal. The usually stated definition of ‘sufficient’ is 30 (see, e.g., Howell [1]). However, this is dependent upon the shape of the distributions. Wilcox [4, 5] discusses a number of situations where, even with relatively large sample sizes, the central limit theorem fails to apply. In particular, the theorem is prone to letting us down when the distributions have heavy tails. This is likely to be the case when the data are derived from a mixed-normal, or contaminated, distribution.

A mixed-normal, or contaminated, distribution occurs when the population comprises of two or more groups, each of which has a different distribution (see **Finite Mixture Distributions**). For example, it may be the case that a measure has a different variance for males and for females, or for alcoholics and nonalcoholics. Wilcox [4] gives an example of a contaminated distribution with two groups. For both subgroups, the mean was equal to zero, for the larger group, which comprised 90% of the population,

4 Central Limit Theory

Figure 6 Sampling distribution of the mean, when $N = 7$, and dice are labelled 1, 1, 1, 2, 2, 3. Bars show sampling distribution, line shows normal distribution with same mean and standard deviation

Figure 7 A normal and a mixed-normal (contaminated) distribution. The normal distribution (solid line) has mean = 0, SD = 1, the mixed normal has mean = 0, SD = 1 for 90% of the population, and mean = 0, SD = 10, for 10% of the population

the standard deviation was equal to 1, while for the smaller subgroup, which comprised 10% of the population, the standard deviation was equal to 10. The population distribution is shown in Figure 7, with a normal distribution for comparison. The shape of the distributions is similar, and probably would not give us cause for concern; however, we should note that the tails of the mixed distribution are heavier.

I generated 100 000 samples, of size 40, from this population. I calculated the mean for each sample, in order to estimate the sampling distribution of the mean. The distribution of the sample means is shown

in the left-hand side of Figure 8. Examining that graph ‘by eye’ one would probably say that it fairly closely approximated a normal distribution. On the right-hand side of Figure 8 the same distribution is redrawn, with a normal distribution curve, with the same mean and standard deviation. We can see that these distributions are different shapes – but is this enough to cause us problems?

The standard deviation of the sampling distribution of these means is equal to 0.48. The mean standard error that was calculated in each sample was 0.44. These values seem close to each other.

Figure 8 Sampling distribution of the mean, with 100 000 samples

6 Central Limit Theory

I also examined how often the 95% **confidence limits** in each sample excluded 0. According to the central limit theorem asymptotically, we would expect that 95% of the samples would have confidence limits that included zero. In this analysis, the figure was 97% – the overestimation of the standard error has caused our type I error rate to drop to 3%. This drop in type I error rate may not seem such a bad thing – we would all like fewer type I errors. However, it must be remembered that along with a drop in type I errors, we must have an increase, of unknown proportion, in type II errors, and hence a decrease in power (*see Power*). (For further discussion of these issues, and possible solutions, see entry on robust statistics.)

Appendix

The following is an R program for carrying out a small Monte Carlo simulation to examine the effect of contaminated distributions on the sampling distribution of the mean. (R is available for most

computer platforms, and can be freely downloaded from www.r-project.org).

Note that any text following a # symbol is a comment and will be ignored by the program; the <– symbol is the assignment operator – to make the variable ‘x’ equal to 3, I would use `x <– 3`.

The program will produce the graph shown in Figure 8, as well as the proportion of the 95% CIs which include the population value (of zero).

Four values are changeable – the first two lines give the SDs for two groups – in the example that was used in the text, the values were 1 and 10.

The third line is used to give the proportion of people in the population in the group with the higher standard deviation – in the example we used 0.1–10%.

Finally, in lines 4 and 5 the sample size and the number of samples to be drawn from the population are given. Again, these are the same as in the example.

```
lowerSD <- 1           #set SD for group with lower SD
upperSD <- 10          #set SD for group with higher SD
proportionInUpper = 0.1 #set proportion of people in group with higher
sampleSize <- 40        #set size of samples
nSamples <- 100000      #set number of samples
#generate data-one variable of length number of samples * sample size.
data <- rnorm(sampleSize * nSamples, 0, lowerSD)+rnorm(sampleSize * nSamples, 0,
  (upperSD-lowerSD)) * rbinom(n=sampleSize * nSamples, size=1,
  p=proportionInUpper)

#Dimension the data to break it into samples
dim(data) <- c(nSamples, sampleSize)

#calculate the mean in each sample
sampleMeans <- rowSums(data) / sampleSize

#generate the labels for the histogram
xAxisLabels <- seq(min(sampleMeans), max(sampleMeans), length=100)
xAxisLabels <- xAxisLabels - mean(sampleMeans) / sd(sampleMeans)

#generate true normal distribution, with same mean and SD as sampling
  distribution, for comparison
NormalHeights <- dnorm(xAxisLabels, mean=mean(sampleMeans), sd=sd(sampleMeans))

#draw histogram, with normal distribution for comparison.
#hist(sampleMeans, probability=TRUE)
heights <- table(round(sampleMeans, 2))
plot(table(round(sampleMeans, 1)))
lines(xAxisLabels, NormalHeights * (nSamples / 10), col="red")
```

```
#Calculate 95% CIs of mean for each sample.
dataSquared <- data^2
dataRowSums <- rowSums(data)
dataRowSumsSquared <- rowSums(dataSquared)
sampleSD <- sqrt((sampleSize*dataRowSumsSquared - dataRowSums^2) / (sampleSize *
  (sampleSize - 1)))
sampleSE <- sampleSD/sqrt(sampleSize)
lowerCIs <- sampleMeans - (sampleSE*(qt(0.975,sampleSize - 1)))
upperCIs <- sampleMeans + (sampleSE*(qt(0.975,sampleSize - 1)))

#check to see if 95% CIs include 0
within95CIs <- lowerCIs < 0 & upperCIs > 0

#draw table of means.
table(within95CIs)
```

The figures shown in the small table earlier refer to the number of samples in which the 95% CIs included the population value of zero. In this run, 96 860 samples (from 100 000, 96.9%) included zero, 3140 (from 100 000, 3.1%) did not. In a normal distribution, and extremely large sample, these values would be 95% and 5%. It may be a worthwhile exercise to set the SDs to be equal, and check to see if this is the case.

To run the program, paste the text into R.

As well as the graph, the output will show a small table:

```
FALSE TRUE
3140 96860
```

Children of Twins Design

One of the first lessons in all statistics classes for the social sciences is that correlation does not mean causation (*see* **Correlation Issues in Genetics Research**). In spite of this premise, most disciplines have historically assumed that associations between parental and offspring characteristics are due to direct environmental causation [15]. However, third variables, or selection factors, may influence both generations and account for the intergenerational relations. Social scientists typically try to statistically control for environmental selection factors in their studies, but unmeasured confounds may also influence the associations. These cannot be controlled statistically. However, unmeasured selection factors can be taken into account by carefully selecting comparison groups, thus moving researchers closer to being able to make causal statements.

Genetic factors are critical to take into account in intergenerational studies, because parents provide the environmental context and transmit their genes to their offspring. Therefore, any statistical association between parents and children may also be due to similar genetic backgrounds. Genetic confounds in intergenerational associations are referred to as passive **gene-environment correlation (passive rGE)**. Passive rGE occurs when common genotypic factors influence parental behaviors, which are considered to be environmental risk factors, and child outcomes [14, 18]. Although genetic confounds render most typical research, such as family studies, uninterruptible, researchers have largely ignored the role of passive rGE [16].

There are a number of behavior genetic designs that delineate between the genetic and environment processes that are responsible for relations between parental characteristics and child outcomes [3, 7, 17]. The most well-known genetically informed design is the **adoption study** because of the clear separation between the genetic risk transmitted to the child by the biological parents and the environment that is provided by the adopting family. However, the adoption study is becoming increasingly difficult to conduct and suffers from a number of methodological assumptions and limitations [17]. The **co-twin control design** can also help separate genetic and environmental processes through which environmental risk factors influence one's behavior, but the

design cannot include risk factors that both twins share [3]. Therefore, other behavior genetic designs are necessary.

The Children of Twins (CoT) Design is a genetically informed approach that also explores the association between environmental risk factors and outcomes in offspring. The offspring of identical twins have the same genetic relationship with their parents and their parents' cotwin because each twin is genetically the same. However, only one twin provides the environment for his/her children. As a result, the genetic risk associated with the parental behavior can be inferred from the cotwin [7, 13]. Using children of identical twins can determine if a parental characteristic has an environmental association with a child behavior or whether the intergenerational relation is confounded by selection factors. When children of fraternal twins are included, the design is able to reveal whether confounds are genetic or environmental in origin [5].

The CoT Design is best known for its use with studying dichotomous environmental risk factors, such as a diagnosis of a psychiatric disorder [6]. For example, the children of schizophrenic parents are at higher risk for developing the disorder than the general population. In order to elucidate the genetic and environmental mechanisms responsible for the intergenerational association, researchers compare the rates of schizophrenia in the offspring of discordant pairs of twins (one twin is diagnosed with the disorder and one is not). A comparison between the children of affected (diagnosed with schizophrenia) identical twins and their unaffected (no diagnosis) cotwins is the initial step in trying to understand the processes through which the intergenerational risk is mediated. Because offspring of both identical twins share the same genetic risk associated with the parental psychopathology from the twins, any difference between the offspring is associated with environmental processes specifically related to the parental psychopathology (see below for a discussion of the influence of the nontwin parent). Effectively, the CoT Design provides the best control comparison group because children with schizophrenia are compared with their cousins who share the same genetic risk associated with schizophrenia and any environmental conditions that the twins share. If offspring from the unaffected identical twin have a lower prevalence of schizophrenia than offspring of the affected identical twin, the results would suggest that

2 Children of Twins Design

the experience of having schizophrenic parent has a direct environmental impact on one's own risk for schizophrenia.

If the rates of the disorder in the offspring of the affected and unaffected identical cotwins are equal to each other, the direct causal role of the parental psychopathology would be undermined. However, such results do not elucidate whether shared genetic or environmental processes are responsible for the intergenerational transmission. A comparison of the rates of psychopathology in the children of the unaffected identical and fraternal cotwins highlights the nature of the selection factors. Children of the unaffected identical twins only vary with respect to the environmental risk associated with schizophrenia, whereas offspring of the unaffected fraternal twin differs with respect to the environmental *and* genetic risk (lower). Therefore, higher rates of schizophrenia in the children of the unaffected identical cotwins than in children of the unaffected fraternal cotwins suggest that genetic factors account for some of the intergenerational covariation. If the rates are similar for the children in unaffected identical and fraternal families, shared environmental factors would be of most import because differences in the level of genetic risk would not influence the rate of schizophrenia.

The most well-known application of the design explored the intergenerational association of schizophrenia using discordant twins [6]. Offspring of schizophrenic identical cotwins had a morbid risk of being diagnosed with schizophrenia of 16.8, whereas offspring of the unaffected identical cotwins had a morbid risk of 17.4. Although the offspring in this later group did not have a parent with schizophrenia, they had the same risk as offspring with a schizophrenic parent. The results effectively discount the direct causal environmental theory of schizophrenia transmission. The risk in the offspring of the unaffected identical twins was 17.4, but the risk was much lower (2.1) in the offspring of the unaffected fraternal cotwins. This latter comparison suggests that genetic factors account for the association between parental and offspring schizophrenia. Similar findings were reported for the transmission of bipolar depression [1]. In contrast, the use of the CoT to explore transmission of alcohol abuse and dependence from parents to their offspring highlighted role of the family environment [8].

One of the main strengths of the design is its ability to study different phenotypes in the parent and

child generations. For example, a study of divorce using the CoT Design reported results consistent with a direct environmental causal connection between parental marital instability and young-adult behavior and substance abuse problems [4]. Similar conclusions were found with CoT Design studies of the association between harsh parenting and child behavior problems [9] and between smoking during pregnancy and child birth weight [3, 11]. However, a CoT analysis found that selection factors accounted for the lower age of menarche in girls growing up in households with a stepfather, results that suggest the statistical association is not a causal relation [12]. These findings suggest that underlying processes in intergenerational associations are dependent on the family risk factors and outcomes in the offspring.

In summary, selection factors hinder all family studies that explore the association between risk factors and child outcomes. Without the ability to experimentally assign children to different conditions, researchers are unable to determine whether differences among groups (e.g., children from intact versus divorced families) are due to the measured risk factor or unmeasured differences between families. Because selection factors may be environmental or genetic in origin, researchers need to use quasi-experimental designs that pull apart the co-occurring genetic and environmental risk processes [17]. The CoT Design is a behavior genetic approach that can explore intergenerational associations with limited methodological assumptions compared to other designs [3]. However, caution must be used when interpreting the result of studies using the CoT Design. Similar to all nonexperimental studies, the design cannot definitely prove causation. The results can only be consistent with a causal hypothesis because environmental processes that are correlated with the risk factor and only influence one twin and their offspring may actually be responsible for the associations.

The CoT Design can also be expanded in a number of ways. The design can include continuously distributed risk factors [3, 7] and measures of family level environments. Associations between parental characteristics and child outcomes may also be due to reverse causation, but given certain assumptions, the CoT Design can delineate between parent-to-child and child-to-parent processes [19]. Because the design is also a quasi-adoption study, the differences in genetic and environmental risk in the approach

provides the opportunity to **gene-environment interaction** [8]. When the spouses of the adult twins are included in the design, the role of **assortative mating** and the influence of both spouses can be considered, an important consideration for accurately describing the processes involved in the intergenerational associations [7]. Finally, the CoT Design can be combined with other behavior genetic designs to test more complex models of parent-child relations [2, 10, 20]. Overall, the CoT Design is an important genetically informed methodology that will continue to highlight the mechanisms through which environmental and genetic factors act and interact.

Chi-Square Decomposition

When analyzing the relationship between two categorical predictors, traditional methods allow one of two decisions: Either the two variables are related or they are not. If they are related, the researcher is not led to further consider the nature of the relationship. This contrasts with the case of a continuous outcome variable, where a significant F in an **analysis of variance (ANOVA)** would be followed up by post hoc tests (*see Multiple Comparison Procedures*). Similarly, with an ANOVA one can do preplanned comparisons if there are hypotheses about where group differences lie. For categorical data, the analogous method is the partition (or decomposition) of chi-square.

Example 1 Relationship Between Two Variables. As a first example, consider the data, reprinted here as Table 1, on race and party identification from the entry **contingency tables** in this encyclopedia. A test of independence reported in that entry led to the conclusion that race and party identification were related; examination of residuals indicated an excess (compared to what would be expected if race and party were independent) of Blacks who were Democrat, and Whites who were Republican. To examine the nature of the relationship using a partition of chi-square, we first calculate the row proportions, reported here in Table 2.

These results are consistent with the previous findings based on residual analysis. The proportion of Blacks who are Democrat is much larger than the proportion of Whites who are Democrat, and the proportion of Whites who are Republican is much larger than the proportion of Blacks who are Republican. Notice also that the proportion of

Table 1 Party identification and race (from the 1991 General Social Survey)

Race	Party identification		
	Democrat	Independent	Republican
White	341	105	405
Black	103	15	11

Table 2 Proportions of each race who have each party identification

Race	Party identification		
	Democrat	Independent	Republican
White	0.401	0.123	0.476
Black	0.798	0.116	0.085

each race who are Independent seems to be about equal.

Although the results here are so obvious that a formal partition of chi-square is somewhat superfluous, I will use this as a simple introduction to the technique. The first step is to introduce another measure used to test models in contingency tables, the likelihood ratio chi-square (*see Contingency Tables*). In the entry on contingency tables, the expected frequencies from the model of independence were compared to the observed frequencies using a measure often represented as X^2 . Here we will call this the Pearson fit statistic. The likelihood ratio fit statistic also compares the observed to the expected frequencies, but using a slightly less obvious formula $G^2 = 2 \sum_i O_i \ln(O_i/E_i)$, where the index i indicates the cell of the table. (The use of a single subscript allows this to apply to tables of any size, including nonrectangular tables.) The utility of this measure of fit will be seen shortly. For the race and party identification data, $G^2 = 90.331$ with 2 degrees of freedom (df); the Pearson statistic was 79.431.

To return to the data, we might hypothesize that (a) Blacks and Whites do not differ in the proportion who register as Independents, and (b) among those who have a party affiliation, Whites are more likely to be Republican than are Blacks. In making these hypotheses, we are dividing the two degrees of freedom for the test of independence into two one-degree-of-freedom parts; we will therefore be partitioning (decomposing) the original fit statistic into two components, each of which corresponds to one of these hypotheses.

The first hypothesis can be tested by using the data in Table 3, where the original three categories of party identification are collapsed into two categories: Independents, and members of a major party.

The value of G^2 for this table is .053 (which is the same as the value of X^2 ; this is often the case

2 Chi-Square Decomposition

Table 3 Race by party identification (independent versus major party)

Race	Party identification	
	Democrat + republican	Independent
White	746	105
Black	114	15

for models that fit well); with 1 df, it is obvious that there is no evidence for a relationship, so we can say that the first hypothesis is confirmed.

We now use the data only on those who are members of a major party to answer the second question. The frequencies are reproduced in Table 4.

Here we find that $G^2 = 90.278$, and $X^2 = 78.908$, each with 1 df. Independence is rejected, and we conclude that among those registered to a major party, there is a large difference between Blacks and Whites in party registration.

Why is this called a partition of chi-square? If we add the likelihood ratio statistics for each of the one df hypotheses, we get $0.053 + 90.278 = 90.331$; this is equal to the likelihood ratio statistic for the full 3×2 table. (The same does not happen for the Pearson statistics; they are still valid tests of these hypotheses, but the results aren't as 'pretty' because they do not produce an exact partition.) We can split the overall fit for the model of independence into parts, testing hypotheses within segments of the overall table.

To get a partition, we must be careful of how we select these hypotheses. Detailed explanations can be found in [3], but a simple general rule is that they correspond to selecting orthogonal contrasts in an ANOVA. For example, the contrast coefficients for testing the first hypothesis (independents versus major party) would be $(-1, 2, -1)$, and the coefficients for comparing Democrats to Republicans would be $(1, 0, -1)$. These two sets of coefficients are orthogonal.

Table 4 Race by party identification (Major party members only)

Race	Party identification	
	Democrat	Republican
White	341	405
Black	103	11

Table 5 Depression in adolescents, by age and sex (Seriously emotionally disturbed only)

Age	Sex	Depression		$P(\text{High})$
		Low	High	
12–14	Male	14	5	.26
	Female	5	8	.62
15–16	Male	32	3	.09
	Female	15	7	.32
17–18	Male	36	5	.12
	Female	12	2	.14

Example 2 Relationships Among Three Variables. Although partitioning is usually applied to two-way tables, it can also be applied to tables of higher dimension. To illustrate a more complex partitioning, I will use some of the data on depression in adolescents from Table 3 of the entry on contingency tables. In that example, there were two groups; I will use only the data on children classified as SED (seriously emotionally disturbed). The remaining variables (age, sex, and depression) give a $3 \times 2 \times 2$ table; my conceptualization will treat age and sex as predictors, and depression as an outcome variable. The data are reproduced in Table 5.

If we consider the two predictors, there are six Age $\times$ Sex groups that form the rows of the table. Therefore, we can think of this as a 6×2 table instead of as a $3 \times 2 \times 2$ table. If we test for independence between the (six) rows and the (two) columns, the likelihood ratio statistic is 18.272 with 5 df. So there is some evidence of a relationship between group and depression. But what is the nature of this relationship? We will start by breaking the overall table into three parts, testing the following three hypotheses:

- (1) the depression rate for males is constant; that is, it does not change with age;
- (2) the depression rate for females is constant;
- (3) the rate of depression in males is the same as that for females.

To test hypothesis (1), we consider Table 6, which contains only the males.

For this table, a test of independence results in a value $G^2 = 3.065$, with 2 df. This is consistent with the hypothesis that the proportion depressed among males does not change with age.

Table 6 Depression in adolescents (Males only)

Age	Depression		<i>P</i> (High)
	Low	High	
12–14	14	5	.26
15–16	32	3	.09
17–18	36	5	.12

Table 7 Depression in adolescents (Females only)

Age	Depression		<i>P</i> (High)
	Low	High	
12–14	5	8	.62
15–16	15	7	.32
17–18	12	2	.14

To test hypothesis (2) we consider Table 7, which is identical in structure to Table 6, but contains only females.

The test of independence here has $G^2 = 6.934$, $df = 2$; this is just significant at the 0.05 level, but the relationship between age and depression is weak. We can further partition the chi-square for this table into two parts. It appears that the highest rate of depression by far among the females is in the youngest age group. Therefore, we will determine whether the 15–16 year-olds have the same level of depression as the 17–18 year-olds, and whether the youngest group differs from the older groups.

To compare 15–16 year-olds with 17–18 year-olds we look only at the last two rows of Table 7, and see whether depression is related to age if we use only those two groups. The value of G^2 is 1.48 with 1 df , so there is no difference in the rate of depression between the two groups. Next we combine these two groups and compare them to the youngest group. The value of G^2 for this table is 5.451 with 1 df , showing that the source of the Age $\times$ Depression relationship in girls is due solely to the youngest group having a higher rate of depression than the two older groups.

To test hypothesis (3), we use the data in Table 8, which is collapsed over age. A test here has $G^2 = 8.27$ with 1 df , so we clearly reject the notion that males and females have equal chances of being depressed. From the proportions in the table, we see that females are more frequently at the high level of depression than males.

Table 8 Depression in adolescents (Collapsed over age)

Sex	Depression		<i>P</i> (High)
	Low	High	
Male	82	13	.137
Female	32	17	.347

To summarize the analyses of these data, the rate of depression in males is constant across the ages measured in this study, but for females there is a somewhat higher rate in the youngest group compared to the two older groups. Finally, males have a lower rate than do females.

Some History and Conclusions

The use of partitioning goes back at least to **Fisher** [1], but was never generally adopted by researchers. Later, partitioning of chi-square was mentioned sporadically through the literature, but often in a mechanical way rather than in a way that corresponded to testing hypotheses of interest to researchers. Further, attempts were made to try to adjust the Pearson chi-square tests so that partitioning was exact; this was unnecessary because (a) the likelihood ratio test will partition exactly, and (b) even without an exact partition, the Pearson fit statistic tests the right hypothesis, and is a valid tool.

Partitioning has an advantage of being extremely simple to understand and implement; the main disadvantage is that some hypotheses cannot easily be tested within this framework. For example, the data on girls in Table 7 indicates the proportion depressed may not change abruptly with age, but instead might decline steadily with age. To test this requires a more general technique called nonstandard **loglinear models** (see e.g., [2]). This technique would also allow us to test all of the hypotheses of interest in one model. A final issue is whether (and how) to adjust probability levels if these techniques are used in a post hoc fashion (see **Multiple Comparison Procedures**). The most frequent suggestion is to use an adjustment similar to a Scheffé test; this would be equivalent to using the critical value for the table as a whole when evaluating any of the subtables in a partition. As with the use of the Scheffé procedure in ANOVA, this is a very conservative approach.

In spite of its limitations, partitioning chi-square allows researchers to test in a clear and simple way

4 Chi-Square Decomposition

many substantive research hypotheses that cannot be tested using traditional methods. For this reason, it deserves to be in the arsenal of all researchers analyzing categorical data.

Cholesky Decomposition

The Cholesky decomposition is a model with as many latent factors as there are observed measures, with no measure-specific variances. The first factor loads on all measures, the second factor loads on all but the first measure, the third factor loads on all but the first two measures, continuing down to the last factor, which loads on only the last measure. This model has the advantage of being of full rank; that is, there are as many parameters being estimated as there are data points. Therefore, a perfect fit to the data will result.

The parameters of the model are contained in the matrix Λ , where,

$$\Lambda = \begin{pmatrix} \lambda_{11} & 0 & 0 \\ \lambda_{21} & \lambda_{22} & 0 \\ \lambda_{31} & \lambda_{32} & \lambda_{33} \end{pmatrix}. \quad (1)$$

The parameters are estimated using **direct maximum-likelihood estimation** for the analysis of raw data. The likelihood function, which is maximized with respect to the Cholesky parameters, is

$$LL = \sum_{i=1}^N \left(-\frac{1}{2} \ln |\Sigma_i| - \frac{1}{2} (\mathbf{x}_i - \boldsymbol{\mu})' \Sigma_i^{-1} (\mathbf{x}_i - \boldsymbol{\mu}) \right), \quad (2)$$

where

- $\mathbf{x}_i$ = vector of scores for a given case (e.g., an individual or twin pair or family)
- Σ_i = appropriate expected covariance matrix for that case
- N = total number of case
- $\boldsymbol{\mu}$ = vector of estimated means

and where

$$2(LL_1 - LL_2) = \chi^2 \quad (3)$$

for testing the difference between two alternative models.

This model can be extended to genetically informative data, such as those obtained from twin pairs, where instead of simply estimating phenotypic covariance structure, we can partition the variance and covariance structure among a twin pair

into genetic ($\mathbf{G}$) and shared ($\mathbf{C}$) and nonshared ($\mathbf{E}$) environmental influences and use the Cholesky decomposition to estimate those partitioned covariance matrices:

$$\Sigma = \begin{pmatrix} \mathbf{G} + \mathbf{C} + \mathbf{E} & r\mathbf{G} + \mathbf{C} \\ r\mathbf{G} + \mathbf{C} & \mathbf{G} + \mathbf{C} + \mathbf{E} \end{pmatrix}, \quad (4)$$

where the top left and bottom right submatrices represent covariances among the multiple measures made within the first and second member of the twin pair, respectively, and the top right and bottom left submatrices represent covariances between those measures taken on twin 1 and with those taken on twin 2. In the above equation, r is 1 for MZ twin pairs and 1/2 for DZ twin pairs. Each quadrant is a function of genetic ($\mathbf{G}$), shared environmental ($\mathbf{C}$) and nonshared environmental ($\mathbf{E}$) covariance matrices, each estimated using a Cholesky decomposition involving $\Lambda_G \Lambda'_G$, $\Lambda_C \Lambda'_C$, and $\Lambda_E \Lambda'_E$, respectively.

Since the maximum-likelihood estimation procedures are performed on unstandardized data, the resulting expected covariance matrices are typically standardized for ease of interpretability. Each of the genetic, shared environmental, and unique environmental covariance matrices, $\mathbf{G}$, $\mathbf{C}$, and $\mathbf{E}$ can be standardized as follows:

$$\mathbf{G}^* = \mathbf{hR}_G \mathbf{h} = \text{diag}(\Sigma_P)^{-\frac{1}{2}} \mathbf{G} \text{diag}(\Sigma_P)^{-\frac{1}{2}} \quad (5)$$

$$\mathbf{C}^* = \mathbf{cR}_C \mathbf{c} = \text{diag}(\Sigma_P)^{-\frac{1}{2}} \mathbf{C} \text{diag}(\Sigma_P)^{-\frac{1}{2}} \quad (6)$$

$$\mathbf{E}^* = \mathbf{eR}_E \mathbf{e} = \text{diag}(\Sigma_P)^{-\frac{1}{2}} \mathbf{E} \text{diag}(\Sigma_P)^{-\frac{1}{2}}, \quad (7)$$

where Σ_P is the expected phenotypic covariance matrix, simply the upper left or bottom right quadrants of either the expected MZ or DZ covariance matrices (since all those quadrants are expected to be equal).

This results in a partitioning of the phenotypic correlation structure among multiple measures, such that these three components, when summed, equal the expected phenotypic correlation matrix. The diagonal elements of the standardized matrices ($\mathbf{G}^*$, $\mathbf{C}^*$, and $\mathbf{E}^*$) contain the heritabilities (*see Heritability*) and proportions of shared and nonshared environmental variance, respectively, for each of the measures. The off-diagonal elements contain what are commonly referred to as the phenotypically standardized genetic

2 Cholesky Decomposition

and environmental covariances. As shown, $\mathbf{G}^*$ can be decomposed into the genetic correlation matrix, $\mathbf{R}_G$, pre- and postmultiplied by the square roots of the heritabilities in a diagonal matrix, $\mathbf{h}$. This

can similarly be done for the shared and nonshared environmental components.

Classical Statistical Inference Extended: Split-Tailed Tests

As pointed out in the entry on **classical statistical inference: practice versus presentation**, classical statistical inference (CSI) as practiced by most researchers is a very useful tool in determining whether sufficient evidence has been marshaled to establish the direction of a population effect. However, classic two-tailed tests, which divide alpha evenly between the rejection regions corresponding to positively and negatively signed values of the population effect, do not take into account the possibility that logic, expert opinion, existing theories, and/or previous empirical studies of this same population effect might strongly (or weakly, for that matter) favor the hypothesis that θ (the population parameter under investigation) is greater than θ_0 (the highly salient dividing line – often zero – between positive and negative population effects) over the alternative hypothesis that $\theta < \theta_0$, or vice versa. The *split-tailed test*, introduced (but not so labeled) by Kaiser [4] and introduced formally by Braver [1], provides a way to incorporate prior evidence into one's significance test so as to increase the likelihood of finding statistical significance in the correct direction (provided that the researchers' assessment of the evidence has indeed pointed her in the correct direction).

The remainder of this article describes the decision rules (DRs) employed in conducting split-tailed significance tests and constructing corresponding confidence intervals. It also points out that the classic one-tailed test (100% of α devoted to the predicted tail of the sampling distribution) is simply an infinitely biased split-tailed test.

Decision Rule(s) for Split-tailed Tests

Split-tailed Statistical Inference (Correlation Coefficient Example)

We test $H_0: \rho_{XY} = 0$ against $H_1: \rho_{XY} > 0$ and $H_2: \rho_{XY} < 0$

by comparing $p_{>} = \Pr(r_{XY} > r_{XY}^* \text{ if } H_0 \text{ were true})$ to $\alpha_{>}$

$$\begin{aligned} \text{and } p_{<} &= \Pr(r_{XY} < r_{XY}^* \text{ if } H_0 \text{ were true}) \\ &= 1 - p_{>} \text{ to } \alpha_{<}. \end{aligned}$$

where r_{XY}^* is the observed value of the correlation coefficient calculated for your sample;

r_{XY} is a random variable representing the values of the sample correlation coefficient obtained from an infinitely large number of independent random samples from a population in which the true population correlation coefficient is precisely zero;

$p_{>}$ is, as the formula indicates, the percentage of the correlation coefficients computed from independent random samples drawn from a population in which $\rho_{XY} = 0$ that are as large as or larger than the one you got for your single sample from that population;

$p_{<}$ is defined analogously as $\Pr(r_{XY} < r_{XY}^* \text{ if } H_0 \text{ were true})$;

$\alpha_{>}$ is the criterion you have set (*before* examining your data) as to how low $p_{>}$ has to be to convince you that the population correlation is, indeed, positive (high values of Y tending to go along with high values of X and low, with low); and

$\alpha_{<}$ is the criterion you have set as to how low $p_{<}$ has to be to convince you that the population correlation is, indeed, negative.

These two comparisons ($p_{<}$ to $\alpha_{<}$ and $p_{>}$ to $\alpha_{>}$) are then used to decide between H_1 and H_2 , as follows:

Decision rule: If $p_{>} < \alpha_{>}$, conclude that (or, at least for the duration of this study, act as if)

H_1 is true (i.e., accept the hypothesis that $\rho_{XY} > 0$).

If $p_{<} < \alpha_{<}$, conclude that (or act as if)

H_2 is true (i.e., accept H_2 that $\rho_{XY} < 0$).

If neither of the above is true (i.e., if $p_{>} \geq \alpha_{>}$ and $p_{<} \geq \alpha_{<}$, which is equivalent to the condition that $p_{>}$ be greater than $\alpha_{>}$ but less than $1 - \alpha_{<}$), conclude that we do not have enough evidence to decide between H_1 and H_2 (i.e., fail to reject H_0).

Split-tailed Statistical Inference (about Other Population Parameters)

As is true for classic (equal-tailed) significance tests, the same basic logic holds for split-tailed tests of any

2 Classical Statistical Inference Extended: Split-Tailed Tests

population effect: the difference between two population means or between a single population mean and its hypothesized value, the difference between a population correlation coefficient and zero, or between two (independent or dependent) correlation coefficients, and so on.

Alternative, but Equivalent Decision Rules

The split-tailed versions of DRs 2 through 3 presented in classical statistical inference: practice versus presentation should be clear. In particular, the rejection-region-based DR 3 can be illustrated as follows for the case of a large-sample t Test of the difference between two sample means (i.e., an attempt to establish the direction of the difference between the two corresponding population means), where the researcher requires considerably stronger evidence to be convinced that $\mu_1 < \mu_2$ than to be convinced that $\mu_1 > \mu_2$ (Figure 1).

Let us modify the example used in the companion entry [3] in which we tested whether interest in Web surfing (Y) increases or decreases with age (X), that is, whether the correlation between Web surfing and age (r_{XY}) is positive (>0) or negative (<0). *Before* collecting any data, we decide that, on the basis of prior data and logic, it will be easier to convince us that the overall trend is negative (i.e., that the overall tendency is for Web-surfing interest to decline with age) than the reverse, so we set $\alpha_<$ to 0.04 and $\alpha_>$ to 0.01. We draw a random sample of 43 US residents five years of age or older, determine each sampled individual's age and interest in Web surfing (measured on a 10-point quasi-interval scale on which high scores represent high interest in Web surfing), and compute the sample correlation between our two measures, which turns out to be -0.31 .

Using Victor Bissonette's statistical applet for computation of the P values associated with sample correlation coefficients (<http://fsweb.berry.edu/academic/education/vbissonnette/applets/sigr.html>), we find that $p_<$ (the probability that an r_{XY} computed on a random sample of size 43 and, thus, $df = 43 - 2 = 41$, drawn from a population in which $\rho_{XY} = 0$, would be less than or equal to -0.31) equals 0.02153. Since this is smaller than 0.04, we reject H_0 in favor of $H_2: \rho_{XY} < 0$.

Had our sample yielded an r_{XY} of $+0.31$, we would have found that $p_> = 0.022$, which is greater than 0.01 (the value to which we set $\alpha_>$), so we would *not* reject H_0 (though we would certainly not accept it), and would conclude that we had insufficient evidence to determine whether ρ_{XY} is positive or negative. Had we simply conducted a symmetric (aka two-tailed) test of H_0 —that is, had we set $\alpha_> = \alpha_< = 0.025$, we would have found in this case that $p_> < \alpha_>$ and we would, therefore, have concluded that $\rho_{XY} > 0$. This is, of course, the price one pays in employing unequal values of $\alpha_>$ and $\alpha_<$: If our pretest assessment of the relative plausibility of H_2 versus H_1 is correct, we will have higher power to detect differences in the predicted direction but lower power to detect true population differences opposite in sign to our expectation than had we set identical decision criteria for positive and negative sample correlations.

A Recommended Supplementary Calculation: The Confidence Interval

The **confidence interval** for the case where we have set $\alpha_<$ to 0.04 and $\alpha_>$ to 0.01, but obtained an r_{XY} of $+0.31$, is instructive on two grounds: First, the

Figure 1 An example: Establishing the sign of a (population) correlation coefficient

bias toward negative values of ρ_{XY} built into the difference between $\alpha_{<}$ and $\alpha_{>}$ leads to a confidence interval that is shifted toward the negative end of the -1 to $+1$ continuum, namely, $-0.047 < \rho_{XY} < 0.535$. Second, it also yields a confidence interval that is wider (range of 0.582) than the symmetric-alpha case (range of 0.547). Indeed, a common justification for preferring $\alpha_{>} = \alpha_{<}$ is that splitting total alpha equally leads to a narrower confidence interval than any other distribution of alpha between $\alpha_{>}$ and $\alpha_{<}$. However, Harris and Vigil ([3], briefly described in Chapter 1 of [2]), have found that the PICI (Prior Information Confidence Interval) around the mean yields asymmetric-case confidence intervals that are, over a wide range of true values of μ , narrower than corresponding symmetric-case intervals. (The PICI is defined as the set of possible values of the population mean that would not be rejected by a split-tailed test, where the $\alpha_{>}$ to $\alpha_{<}$ ratio employed decreases as an exponential function of the particular value of μ being tested, asymptotically approaching unity and zero for infinitely small and infinitely large values of μ , and equals 0.5 for the value of μ that represents the investigator's *a priori* estimate of μ .) Since the CI for a correlation is symmetric around the sample correlation when expressed in Fisher- z -transformed units, it seems likely that applying PICIs around correlation coefficients would also overcome this disadvantage of splitting total alpha unequally.

Power of Split-tailed versus One- and Two (Equal)-Tailed Tests

A common justification for using one-tailed tests is that they have greater power (because they employ lower critical values) than do two-tailed tests. However, that is true only if the researcher's hypothesis about the direction of the population effect is indeed correct; if the population effect differs in sign from that hypothesized, the power of his one-tailed test of his hypothesis cannot exceed $\alpha/2$ – and all of even that low power is actually Type III error, that is, represents cases where the researcher comes to the incorrect conclusion as to the direction of the population effect. Further, the power advantage of a one-tailed test (i.e., a split-tailed test with infinite bias in favor of one's research hypothesis) over a split-tailed test with, say, a 50-to-1 bias is miniscule when the research hypothesis is correct, and the latter

test has much higher power than the one-tailed test when the researcher is mistaken about the sign of the population effect.

To demonstrate the above points, consider the case where IQ scores are, for the population under consideration, distributed normally with a population mean of 105 and a population standard deviation of 15. Assume further that we are interested primarily in establishing whether this population's mean IQ is above or below 100, and that we propose to test this by drawing a random sample of size 36 from this population. If we conduct a two-tailed test of this effect, our power (the probability of rejecting H_0) will be 0.516, and the width of the 95% CI around our sample mean IQ will be 9.8 IQ points. If, on the other hand, we conduct a one-tailed test of H_r that $\mu > 100$, our power will be 0.639 – a substantial increase. If, however, our assessment of prior evidence, expert opinion, and so on, has led us astray and we, instead, hypothesize that $\mu < 100$, our power will be a miniscule 0.00013 – and every bit of that power will come from cases where we have concluded incorrectly that $\mu < 100$. Further, since no sample value on the nonpredicted side of 100 can be rejected by a one-tailed test, our confidence interval will be infinitely wide. Had we instead conducted a split-tailed test with 'only' a 49-to-1 bias in favor of our H_r , our power would have been 0.635 (0.004 lower than the one-tailed test's power) if our prediction was correct and 0.1380 if our prediction was incorrect (over a thousand times higher than the one-tailed test's power in that situation); only 0.0001 of that power would have been attributable to Type III error; and our confidence intervals would each have the decidedly noninfinite width of 11.9 IQ points.

In my opinion, the very small gain in power from conducting a one-tailed test of a correct H_r , rather than a split-tailed test, is hardly worth the risk of near-zero power (all of it actually Type III error), the certainty of an infinitely wide confidence interval, and the knowledge that one has violated the principle that scientific hypotheses must be disconfirmable that come along with the use of a one-tailed test. Small surprise, then, that the one-tailed test was *not* included in the companion entry's description of Classical Statistical Inference in scientifically sound practice (see **Classical Statistical Inference: Practice versus Presentation**).

4 Classical Statistical Inference Extended: Split-Tailed Tests

Practical Computation of Split-tailed Significance Tests and Confidence Intervals

Tables of critical values and some computer programs are set up for one-tailed and two-tailed tests at conventional (usually 0.05 and 0.01 and, sometimes, 0.001) alpha levels. This makes sense; it would, after all, be impossible to provide a column for every possible numerical value that might appear in the numerator or denominator of the $\alpha_{>} / \alpha_{<}$ ratio in a split-tailed test. If the computer program you use to compute your test statistic does not provide the P value associated with that test statistic (which would, if provided, permit applying DR 1), or if you find yourself relying on a table or program with only 0.05 and 0.01 levels, you can use the 0.05 one-tailed critical value (aka the 0.10-level two-tailed critical value) in the predicted direction and the 0.01-level one-tailed test in the nonpredicted direction for a 5-to-1 bias in favor of your research hypothesis, and a total alpha of 0.06 – well within the range of uncertainty about the true alpha of a nominal 0.05-level test, given all the assumptions that are never perfectly satisfied. Or, you could use the 0.05-level and 0.001-level critical values for a 50-to-1 bias and a total alpha of 0.051.

Almost all statistical packages and computer sub-routines report only symmetric confidence intervals. However, one can construct the CI corresponding to a split-tailed test by combining the lower bound of a $(1-2\alpha_{>})$ -level symmetric CI with the upper bound of a $(1-2\alpha_{<})$ -level symmetric CI. This also serves as a rubric for hand computations of CIs to accompany split-tailed tests. For instance, for the example used to demonstrate relative power ($H_0 : \mu_Y = 100$, Y distributed normally with a *known* population standard deviation of 15 IQ points, $\alpha_{>} = 0.049$ and $\alpha_{<} = 0.001$, sample size = 36 observations), if our sample mean equals 103, the corresponding CI will extend from $103 - 1.655(2.5) = 98.8625$ (the lower bound of a 0.902-level symmetric CI around 103) to $103 + 3.090(2.5) = 110.725$ (the upper bound of the 0.998-level symmetric CI). For comparison, the CI corresponding to a 0.05-level one-tailed test with $H_r: \mu_Y > 100$ (i.e., an infinitely biased split-tailed test with $\alpha_{>} = 0.05$ and $\alpha_{<} = 0$) would extend from $103 - 1.645(2.5) = 98.89$ to $103 + \infty(2.5) = +\infty$ – or, perhaps, from 100 to $+\infty$, since the primary presumption of the one-tailed

test is that we do not accept the possibility that μ_Y could be < 100 .

Choosing an $\alpha_{>}/\alpha_{<}$ Ratio

The choice of how strongly to bias your test of the sign of the population effect being estimated in favor of the direction you believe to be implied by logic, theoretical analysis, or evidence from previous empirical studies involving this same parameter is ultimately a subjective one, as is the choice as to what overall alpha ($\alpha_{>} + \alpha_{<}$) to employ. One suggestion is to consider how strong the evidence for an effect opposite in direction to your prediction must be before you would feel compelled to admit that, under the conditions of the study under consideration, the population effect is indeed opposite to what you had expected it to be. Would a sample result that would have less than a one percent chance of occurring do it? Would a $p_{<}$ of 0.001 or less be enough? Whatever the breaking point for your prediction is (i.e., however low the probability of a result as far from the value specified in H_0 in the direction opposite to prediction as your obtained results has to be to get you to conclude that you got it wrong), make that the portion of alpha you assign to the nonpredicted tail.

Alternatively and as suggested earlier, you could choose a ratio that is easy to implement using standard tables, such as 0.05/0.01 or 0.05/0.001, though that requires accepting a slightly higher overall alpha (0.06 or 0.051, respectively, in these two cases) than the traditional 0.05.

Finally, as pointed out by section editor Randal Macdonald (personal communication), you could leave to the reader the choice of the $\alpha_{>}/\alpha_{<}$ ratio by reporting, for example, that the effect being tested would be statistically significant at the 0.05 level for all $\alpha_{>}/\alpha_{<}$ ratios greater than 4.3. Such a statement can be made for some finite ratio if and only if $p_{>} < \alpha$ – more generally, if and only if the obtained test statistic exceeds the one-tailed critical value for the obtained direction. For instance, if a t Test of $\mu_1 - \mu_2$ yielded a positive sample difference (mean for first group greater than mean for second group) with an associated $p_{>}$ of 0.049, this would be considered statistically significant evidence that $\mu_1 > \mu_2$ by any split-tailed test with an overall alpha of 0.05 and an $\alpha_{>}/\alpha_{<}$ ratio of $0.049/0.001 = 49$ or greater. If the obtained $p_{>}$ were 0.003, then the difference would be declared statistically significant evidence

that $\mu_1 > \mu_2$ by any split-tailed test with an overall alpha of 0.05 and an $\alpha_{>}/\alpha_{<}$ ratio of $0.003/0.997 = 0.00301$ or more – that is, even by readers whose bias in favor of the hypothesis that $\mu_1 < \mu_2$ led them to employ an $\alpha_{<}/\alpha_{>}$ ratio of $0.997/0.003 = 332.3$ or less. But if the obtained $p_{>}$ were 0.052, no split-tailed test with an overall alpha of 0.05 would yield statistical significance for this effect, no matter how high the preferred $\alpha_{>}/\alpha_{<}$ ratio. The one-tailed critical value, thus, can play a role as the basis for a preliminary test of whether the difference might be statistically significant by any split-tailed test – provided (in my opinion) that the researcher does not ‘buy into’ the associated logic of a one-tailed test by employing an infinitely large ratio of predicted to nonpredicted rejection-region area.

Wrapping Up

Finally, this entry should *not* be taken as an endorsement of split-tailed tests in preference to two-tailed tests. Indeed, my personal preference and habit is to rely almost exclusively on two-tailed tests and, thereby, let the data from the study in hand completely determine the decision as to which of that

study’s results to consider statistically significant. On the other hand, if you find yourself tempted to carry out a one-tailed test because of strong prior evidence as to the sign of a population parameter, a split-tailed test is, in my opinion, a far sounder approach to giving into that temptation than would be a one-tailed test.

Classical Statistical Inference: Practice versus Presentation

Classical statistical inference as practiced by most researchers is a very useful tool in determining whether sufficient evidence has been marshaled to establish the direction of a population effect. Classical statistical inference (CSI) as described in almost all textbooks forces the researcher who takes that description seriously to choose among affirming a truism, accepting a falsehood on scant evidence, or violating one of the most fundamental tenets of scientific method by declaring one's research hypothesis impervious to disconfirmation. Let us start with the positive side of CSI.

As has often been pointed out (e.g., [7]) CSI has evolved over many decades as a blending of Fisherian and Neyman-Pearson approaches. I make no attempt in this entry to identify the traces of those traditions in current practice, but focus instead on the consensus that has emerged. (But see [7, 14], and **Deductive Reasoning and Statistical Inference; Neyman-Pearson Inference.**)

CSI in (Sound) Practice

Purpose

The test of statistical significance that is the core tool of CSI is a test of the sign or direction of some population effect: the sign of a population correlation coefficient; the slope (positive versus negative) of a population regression coefficient; which of two population means is larger (and thus whether the sign of the difference between the two means is positive or negative); whether attitudes towards a politician are, on average and in the population, positive or negative (and thus whether the population mean attitude score minus the midpoint of the scale is positive or negative); whether the students in a given state have a mean IQ above or below 100 (and thus whether mean IQ minus 100 is positive or negative); and so on (see **Catalogue of Parametric Tests**).

Underlying Logic

We attempt to establish the sign of the population effect via the also-classic method of *reductio ad absurdum*. We set up a straw-man null hypothesis that the true population effect size is precisely zero (or equivalently, that the population parameter representing the effect has a value that precisely straddles the dividing line between positive and negative or between increasing and decreasing or between $\mu_1 > \mu_2$ and $\mu_1 < \mu_2$) and then proceed to marshal sufficient evidence to disprove this least interesting possibility.

If we cannot disprove the hypothesis that the population effect size is exactly zero, we will also be unable to disprove either the hypothesis that it equals $+10^{-24}$ (pounds or meters or units on a 10-point scale) or the hypothesis that it equals -10^{-31} . In other words, both positive and negative (increasing and decreasing, etc.) values of the population effect size could have generated our data, and we thus cannot come to any conclusion about the sign or direction of the population effect. If, on the other hand, we are able to reject the straw-man null hypothesis – that is, our observed sample effect size is too much greater or less than zero to have been generated plausibly via sampling from a population in which the null hypothesis is exactly true – then we will also be able to reject all hypotheses that the true population effect size is even more distant from zero than our observed sample effect size. In other words, all plausible values of the effect size will have the same sign as our sample effect size, and we will be safe in concluding that the population and sample effect sizes have the same sign.

Put another way, failure to reject the null hypothesis implies that the **confidence interval** around our sample effect size includes both positive and negative values, while rejecting H_0 implies that the confidence interval includes only negative or only positive values of the effect size.

Ordinarily, we should decide before we begin gathering the data on which to base our test of statistical significance what degree of implausibility will be sufficient to reject the null hypothesis or, equivalently, what confidence level we will set in establishing a confidence interval around the observed sample effect size. The decision as to how stringent a criterion to set for any particular significance test may hinge on what other tests we plan to perform on other

2 Classical Statistical Inference: Practice versus Presentation

aspects of the data collected in the present study (*see Multiple Comparison Procedures.*)

Decision Rule(s), Compactly Presented

The last few paragraphs can be summarized succinctly in the following more formal presentation of the case in which our interest is in whether the correlation between two variables, X and Y , is positive or negative.

Scientifically Sound Classical Statistical Inference (Correlation Coefficient Example).

We test $H_0: \rho_{XY} = 0$ against $H_1: \rho_{XY} > 0$ and $H_2: \rho_{XY} < 0$

by comparing $p_{>} = P(r_{XY} > r_{XY}^* \text{ if } H_0 \text{ were true})$ to $\alpha/2$ and

$p_{<} = P(r_{XY} < r_{XY}^* \text{ if } H_0 \text{ were true}) = 1 - p_{>}$ to $\alpha/2$, where

r_{XY}^* is the observed value of the correlation coefficient calculated for your sample;

r_{XY} is a random variable representing the values of the sample correlation coefficient obtained from an infinitely large number of independent random samples from a population in which the true population correlation coefficient is precisely zero;

$p_{>}$ is, as the formula indicates, the percentage of the correlation coefficients computed from independent random samples drawn from a population in which $\rho_{XY} = 0$ that are as large as or larger than the one you got for your single sample from that population;

$p_{<}$ is defined analogously as $P(r_{XY} < r_{XY}^* \text{ if } H_0 \text{ were true})$; and

α is the criterion you have set (*before* examining your data) as to how low $p_{>}$ or $p_{<}$ has to be to convince you that the population correlation is, indeed, positive (high values of Y tending to go along with high values of X and low, with low).

These two comparisons ($p_{<}$ to $\alpha_{<}$ and $p_{>}$ to $\alpha_{>}$) are then used to decide between H_1 and H_2 , as follows:

Decision rule: If $p_{>} < \alpha/2$, conclude that (or, at least for the duration of this study, act as if)

H_1 is true. (I.e., accept the hypothesis that $\rho_{XY} > 0$.)

If $p_{<} < \alpha/2$, conclude that (or act as if)

H_2 is true. (I.e., accept H_2 that $\rho_{XY} < 0$.)

If neither of the above is true (i.e., if $p_{>}$ and $p_{<}$ are both $\geq \alpha/2$ which is

equivalent to the condition that $p_{>}$ be greater than $\alpha/2$ but less than $1 - \alpha/2$),

conclude that

we don't have enough evidence to decide between H_1 and H_2 .

(i.e., fail to reject H_0 .)

Scientifically Sound Classical Statistical Inference About Other Population Parameters.

To test whether any other population parameter θ (e.g., the population mean, the difference between two population means, the difference between two population correlations) is greater than or less than some especially salient value θ_0 that represents the dividing line between a positive and negative effect (e.g., 100 for mean IQ, zero for the difference between two means or the difference between two correlations), simply substitute θ (the parameter of interest) for ρ_{XY} , $\hat{\theta}^*$ (your sample estimate of the parameter of interest, that is, the observed value in your sample of the statistic that corresponds to the population parameter) for r_{XY}^* , and θ_0 for zero (0) in the above.

The above description is silent on the issue of how one goes about computing $p_{>}$ and/or $p_{<}$. This can be as simple as conducting a single-sample z test or as complicated as the lengthy algebraic formulae for the test of the significance of the difference between two correlation coefficients computed on the same sample [17]. See your local friendly statistics textbook or journal or the entries on various significance tests in this encyclopedia for details (*see Catalogue of Parametric Tests*).

An Example: Establishing the Sign of a (Population) Correlation Coefficient

For example, let's say that we wish to know whether interest in Web surfing (Y) increases or decreases with age (X), that is, whether the correlation between Web surfing and age (r_{XY}) is positive (>0) or negative (<0). *Before* collecting any data we decide to set α to 0.05. We draw a random sample of 43 US residents 5 years of age or older, determine each sampled individual's age and interest in Web surfing (measured on a 10-point quasi-interval scale on which high scores represent high interest in Web surfing), and compute the sample correlation between our two measures, which turns out to be -0.31 . (Of course, this relationship is highly likely to be curvilinear, with few 5-year-olds expressing much interest in Web

surfing; we're testing only the overall linear trend of the relationship between age and surfing interest. Even with that qualification, before proceeding with a formal significance test we should examine the scatterplot of Y versus X for the presence of **outliers** that might be having a drastic impact on the slope of the best-fitting straight line and for departures from normality in the distributions of X and Y so extreme that transformation and/or nonparametric alternatives should be considered.)

Using Victor Bissonette's statistical applet for computation of the P values associated with sample correlation coefficients (<http://fsweb.berry.edu/academic/education/vbissonnette/applets/sigr.html>), we find that $p_<$ (the probability that an r_{XY} computed on a random sample of size 43 and thus $df = 43 - 2 = 41$, drawn from a population in which $\rho_{XY} = 0$, would be less than or equal to -0.31) equals 0.02153. Since this is smaller than $0.05/2 = 0.025$, we reject H_0 in favor of H_2 : $\rho_{XY} < 0$.

Had our sample yielded an r_{XY} of $+0.28$ we would have found that $p_< = 0.965$ and $p_> = 0.035$, so we would *not* reject H_0 (though we would certainly not accept it) and would conclude that we had insufficient evidence to determine whether ρ_{XY} is positive or negative. (It passeth all plausibility that it could be precisely 0.000... to even a few hundred decimal places.)

A Recommended Supplementary Calculation: The Confidence Interval

It is almost always a good idea to supplement any test of statistical significance with the confidence interval around the observed sample difference or correlation (Harlow, Significance testing introduction and overview, in [9]). The details of how and why to do this are covered in the confidence interval entry in this encyclopedia (see **Confidence Intervals**). To reinforce its importance, however, we'll display the confidence intervals for the two subcases mentioned above.

First, for the sample r_{XY} of $+0.31$ with $\alpha = 0.05$, the 95% confidence interval (CI) around (well, attempting to capture) ρ_{XY} is $0.011 < \rho_{XY} < 0.558$. (It can be obtained via a plug-in program on Richard Lowry's VassarStats website, <http://faculty.vassar.edu/lowry/rho.html>.) The lower bound of this interval provides a useful caution against

confusing statistical significance with magnitude or importance, in that it tells us that, while we can be quite confident that the population correlation is positive, it could plausibly be as low as 0.011. (For example, our data are insufficient to reject the null hypothesis that $\rho_{XY} = 0.02$, that is that the two variables share only 0.04% of their variance).

The case where we obtained an r_{XY} of $+0.28$ yields a 95% CI of $-0.022 < \rho_{XY} < 0.535$. No value contained within the 95% CI can be rejected as a plausible value by a 0.05-level significance test, so that it is indeed true that we cannot rule out zero as a possible value of ρ_{XY} , which is consistent with our significance test of r_{XY} . On the other hand, we also can't rule out values of -0.020 , $+0.200$, or even $+0.50$ – a population correlation accounting for 25% of the variation in Y on the basis of its linear relationship to X . The CI thus makes it abundantly clear how foolish it would be to accept (rather than fail to reject) the null hypothesis of a population correlation of precisely zero on the basis of statistical nonsignificance.

Alternative, but Equivalent Decision Rules

DR (Decision Rule) 2

If either $p_>$ or $p_<$ is $< \alpha/2$ and the sample estimate of the population effect is positive ($\hat{\theta} > \theta_0$, for example, r_{XY}^* positive or sample mean IQ > 100) reject H_0 and accept H_1 that $\theta > \theta_0$ (e.g., that $\rho_{XY} > 0$).

If either $p_>$ or $p_<$ is $< \alpha/2$ and the sample estimate of the population effect is negative ($\hat{\theta} < \theta_0$, for example, $r_{XY}^* < 0$ or sample mean IQ < 100) reject H_0 and accept H_1 that $\theta < \theta_0$ (e.g., that the population correlation is negative or that the population mean IQ is below 100).

DR 3. First, select a test statistic T that, for fixed α and sample size, is monotonically related to the discrepancy between $\hat{\theta}$ and θ_0 . (Common examples would be the z - or t ratio for the difference between two independent or correlated means and the chi-square test for the difference between two independent proportions.) Compute T^* (the observed value of T for your sample). By looking it up in a table or using a computer program (e.g., any of the widely available online statistical applets, such as those on Victor Bissonnette's site, cited earlier),

4 Classical Statistical Inference: Practice versus Presentation

determine either the two-tailed P value associated with T^* or T_{crit} , the value of T^* that would yield a two-tailed P value of exactly α . (The ‘two-tailed P value’ equals twice the smaller of $p_>$ or $p_<$ – that is, it is the probability of observing a value of T as large as or larger than T^* in absolute value in repeated random samplings from a population in which H_0 is true.) Then, if $p < \alpha$ or if $|T^*|$ (the absolute value of T^* , that is, its numerical value, ignoring sign) is greater than T_{crit} , conclude that the population effect has the same sign as the sample effect – that is, accept whichever of H_1 or H_2 is consistent with the data. If instead $|T^*| < T_{\text{crit}}$, conclude that we don’t have enough evidence to decide whether $\theta > \theta_0$ or $< \theta_0$ (e.g., whether ρ_{XY} is positive or negative).

This decision rule is illustrated below in Figure 1 for the case of a large-sample t Test of the difference between two sample means (i.e., an attempt to establish the direction of the difference between the two corresponding population means) where the researcher has set α to 0.05.

DR 4. Construct the $(1 - \alpha)$ -level confidence interval (CI) for θ corresponding to your choice of α and to $\hat{\theta}^*$, the value of $\hat{\theta}$ you obtained for your sample of observations. (See the entry in this encyclopedia on confidence intervals for details of how to do this.) Then

- If the CI includes only values that are $> \theta_0$, conclude that $\theta > \theta_0$.
- If the CI includes only values that are $< \theta_0$, conclude that $\theta < \theta_0$.
- Otherwise (i.e., if the CI includes some values that are $> \theta_0$ and some that are $< \theta_0$), conclude that we

don’t have enough evidence to decide whether $\theta > \theta_0$ or $< \theta_0$.

As applied to testing a single, one-degree-of-freedom hypothesis the above six decision rules are logically and algebraically equivalent and therefore lead to identical decisions when applied to any given sample of data. However, Decision Rule DR 4 (based on examination of the confidence interval around the sample estimate) actually encompasses an infinity of significance tests, since it neatly partitions the real line into values of θ that our data disconfirm (to within the ‘reasonable doubt’ quantified by α) and those that are not inconsistent with our data. This efficiency adds to the argument that confidence intervals could readily replace the use of significance tests as represented by DRs 1–3. However, this efficiency comparison is reversed when we consider multiple-degree-of-freedom (aka ‘overall’) significance tests, since an appropriate overall test tells us whether any of the infinite number of single- df contrasts is (or would be, if tested) statistically significant.

Criticisms of and Alternatives to CSI

The late 1990’s saw a renewal of a recurring cycle of criticism of classical statistical inference, including a call by Hunter [10] for a ban on the reporting of null-hypothesis significance tests (NHSTs) in APA journals. The history of this particular cycle is recounted by Fidler [6]; a compilation of arguments for and against NHST is provided by [10].

Figure 1 An example: Establishing the direction of the difference between two population means

Briefly, the principal arguments offered against NHST (aka CSI) are that

- (a) It wastes the researcher's time testing an hypothesis (the null hypothesis) that is never true for real variables.
- (b) It is misinterpreted and misused by many researchers, the most common abuse being treating a nonsignificant result (failure to reject H_0) as equivalent to accepting the null hypothesis.
- (c) It is too rigid, treating a result whose P value is just barely below α (e.g., $p = .0498$) as much more important than one whose P value is just barely above α (e.g., $p = .0501$).
- (d) It provides the probability of the data, given that H_0 is true, when what the researcher really wants to know is the probability that H_0 is true, given the observed data.
- (e) There are alternatives to NHST that have much more desirable properties, for example (i) Bayesian inference (see **Bayesian Statistics**), (ii) effect sizes (see **Effect Size Measures**), (iii) confidence intervals, and (iv) **meta-analysis**.

Almost equally briefly, the counterarguments to the above arguments are that

- (a) As pointed out earlier, we test H_0 , not because anyone thinks it might really be true, but because, if we can't rule out θ_0 (the least interesting possible value of our population parameter, θ), we also can't rule out values of θ that are both greater than and smaller than θ_0 – that is, we won't be able to establish the sign (direction) of our effect in the population, which is what significance testing (correctly interpreted) is all about.
- (b) That NHST is often misused is an argument for better education, rather than for abandoning CSI. We certainly do need to do a better job of presenting CSI to research neophytes – in particular, we need to expunge from our textbooks the traditional, antiscientific presentation of NHST as involving a choice between two, rather than three, conclusions.
- (c) Not much of a counterargument to this one. It seems compelling that confidence in the direction of an effect should be a relatively smooth, continuous function of the strength of the evidence against the null hypothesis (and thus,

more importantly, against the hypothesis that the population effect is opposite in sign to its sample estimate). In practice (as Estes [5] explicitly states for himself but also opines is true for most journal editors), a result with an associated P value of 0.051 is unlikely to lead to an automatic decision not to publish the report – unless the editor feels strongly that the most appropriate alpha level for translating the continuous confidence function into a discrete, 'take it seriously' versus 'require more data and/or replication' decision is 0.01 or 0.001. The adoption as a new 'standard' of an overall alpha ($\alpha_+ + \alpha_-$) greater than 0.05 (say, 0.055) is unlikely, however, for at least two reasons: First, such a move would simply transfer the frustration of 'just missing' statistical significance and the number of complaints about the rigidity of NHST from researchers whose P values have come out to 0.51 or 0.52 to those with P values of 0.56 or 0.57. Second, as a number of authors (e.g., Wainer & Robinson [18]) have documented, 0.05 is already a more liberal alpha level than the founders of CSI had envisioned and than is necessary to give reasonable confidence in the replicability of a finding (e.g., Greenwald, et al. [8], who found that a P value of 0.005 – note the extra zero – provides about an 80% chance that the finding will be statistically significant at the 0.05 level in a subsequent exact replication).

- (d) This one is just flat wrong. Researchers are *not* interested in (or at least shouldn't be interested in) the probability that H_0 is true, since we know *a priori* that it is almost certainly *not* true. As suggested before, most of the ills attributed to CSI are due to the misconception that we can *ever* collect enough evidence to demonstrate that H_0 is true to umpteen gazillion decimal places.
- (e)
 - (i) Bayesian statistical inference (BSI) is in many ways a better representation than CSI of the way researchers integrate data from successive studies into the belief systems they have built up from a combination of logic, previous empirical findings, and perhaps unconscious personal biases. BSI requires that the researcher make her belief

system explicit by spelling out the prior probability she attaches to every possible value of the population parameter being estimated and then, once the data have been collected, apply Bayes' Theorem to modify that distribution of prior probabilities in accordance with the data, weighted by their strength relative to the prior beliefs. However, most researchers (though the size of this majority has probably decreased in recent years) feel uncomfortable with the overt subjectivity involved in the specification of prior probabilities. CSI has the advantage of limiting subjectivity to the decision as to how to distribute total alpha between $\alpha_> + \alpha_<$. Indeed, split-tailed tests (cf. **Classical Statistical Inference Extended: Split-Tailed Tests**) can be seen as a 'back door' approach to Bayesian inference.

- (ii) Confidence intervals are best seen as complementing, rather than replacing significance tests. Even though the conclusion reached by a significance test of a particular θ_0 is identical to that reached by checking whether θ_0 is or is not included in the corresponding CI, there are nonetheless aspects of our evaluation of the data that are much more easily gleaned from one or the other of these two procedures. For instance, the CI provides a quick, easily understood assessment of whether a non-significant result is a result of a population effect size that is very close to zero (e.g., a CI around mean IQ of your university's students that extends from 99.5 to 100.3) or is instead due to a sloppy research design (high variability and/or low sample size) that has not narrowed down the possible values of θ_0 very much (e.g., a CI that states that population mean IQ is somewhere between 23.1 and 142.9). On the other hand, the P value from a significance test provides a measure of the confidence you should feel that you've got the sign of the population effect right. Specifically, the probability that you have declared $\theta - \theta_0$ to have the wrong sign is at most half of the P value for a two-tailed significance test. The P value is also directly related

to the likelihood that an exact replication would yield statistical significance in the same direction [8]. Neither of these pieces of information is easily gleaned from a CI except by rearranging the components from which the CI was constructed so as to reconstruct the significance test. Further, the P value enables the reader to determine whether to consider an effect statistically significant, regardless of the alpha level he or she prefers, while significance can be determined from a confidence interval only for the alpha level chosen by the author. In short, we need both CIs and significance tests, rather than either by itself.

- (iii) In addition to the issue of the sign or direction of a given population effect, we will almost always be interested in how large an effect is, and thus how important it is on theoretical and/or practical/clinical grounds. That is, we will want to report a measure of *effect size* for our finding. This will often be provided implicitly as the midpoint of the range of values included in the confidence interval – which, for symmetrically distributed $\hat{\theta}$, will also be our point estimate of that parameter. However, if the units in which the population parameter being tested and its sample estimate are expressed are arbitrary (e.g., number of items endorsed on an attitude inventory) a *standardized* measure of effect size, such as Cohen's d , may be more informative. (Cohen's d is, for a single- or two-sample t Test, the observed difference divided by the best available estimate of the standard deviation of $\hat{\theta}$) However, worrying about size of effect (e.g., how *much* a treatment helps) is usually secondary to establishing *direction* of effect (e.g., whether the treatment helps or harms).
- (iv) The 'wait for the *Psych Bull* article' paradigm was old hat when I entered the field lo those many decades ago. This paradigm acknowledges that any one study will have many unique features that render generalization of its findings hazardous, which is the basis for the statement earlier in this entry that a 'conclusion' based on a significance test is limited in scope to the

present study. For the duration of the report of the particular study in which a given significance test occurs we agree to treat statistically significant effects as if they indeed matched the corresponding effect in sign or direction, even though we realize that we may have happened upon the one set of unique conditions (e.g., the particular on/off schedule that yielded ulcers in the classic ‘executive monkey’ study [2]) that yields this direction of effect. We gain much more confidence in the robustness of a finding if it holds up under replication in different laboratories, with different sources of respondents, different researcher biases, different operational definitions, and so on. Review articles (for many years but no longer a near-monopoly of *Psychological Bulletin*) provide a summary of how well a given finding or set of findings holds up under such scrutiny. In recent decades the traditional ‘head count’ (tabular review) of what proportion of studies of a given effect yielded statistical significance under various conditions has been greatly improved by the tools of meta-analysis, which emphasizes the recording and analysis of an effect-size measure extracted from each reviewed study, rather than simply the dichotomous measure of statistical significance or not. Thus, for instance, one study employing a sample of size 50 may find a statistically nonsignificant correlation of 0.14, while another study finds a statistically significant correlation of 0.12, based on a sample size of 500. Tabular review would count these studies as evidence that about half of attempts to test this relationship yield statistical significance, while meta-analysis would treat them as evidence that the effect size is in the vicinity of 0.10 to 0.15, with considerable consistency (low variability in obtained effect size) from study to study. Some authors [e.g., [16]] have extolled meta-analysis as an alternative to significance testing. However, meta-analytic results, while based on larger sample sizes than any of the single studies

being integrated, are not immune to sampling variability. One would certainly wish to ask whether effect size, averaged across studies, is statistically significantly higher or lower than zero. In other words, conducting a meta-analysis does not relieve one of the responsibility of testing the strength of the evidence that the population effect has a particular sign or direction.

CSI As Presented (Potentially Disastrously) in Most Textbooks

Here’s where I attempt to document the ‘dark side’ of classical statistical inference, namely, the overwhelming tendency of textbooks to present its logic in a way that forces the researcher who takes it seriously to choose between vacuous versus scientifically unsound conclusions. Almost all such presentations consider two DRs: the *two-tailed test* (related to the two-tailed P value defined earlier, as well as to DRs 1–3) and the *one-tailed test*, in which the sign of the population effect is considered to be known *a priori*.

Two-tailed Significance Test (Traditional Textbook Presentation)

DR 2T. Compute (or, more likely, look up) the two-tailed critical value of symmetrically distributed test statistic T , T_{crit} . This is the $100(1-\alpha/2)$ th percentile of the sampling distribution of T , that is the value of T such that $100(\alpha/2)\%$ of the samples drawn from a population in which H_0 is true would yield a value of T that is as far from θ_0 as (or even farther from θ_0 than) that critical value, in either direction. Then

If $|T^*|$ (the absolute value of the observed value of T in your sample) is $>cv_{\alpha/2}$, accept H_1 that $\theta \neq \theta_0$.
If $|T^*|$ is $<T_{\text{crit}}$, that is, if $-T_{\text{crit}} < T^* < T_{\text{crit}}$, do not reject H_0 that $\theta = \theta_0$.

An even more egregious but unfortunately common variation of DR 2T replaces the ‘do not reject H_0 ’ decision with the injunction to ‘accept H_0 ’.

This decision rule can be illustrated for the same case (difference between two means) that was used to illustrate DR 3 as follows (Figure 2):

Figure 2 Two-tailed test as presented in (almost all) textbooks

Figure 3 One-tailed Test

One-tailed Significance Test (Traditional Textbook Presentation)

DR 1T: Compute (or, more likely, look up) the one-tailed critical value of symmetrically distributed test statistic T , cv_α . This is either the negative of the α th percentile or the $100(1-\alpha)$ th percentile of the sampling distribution of T , that is the value of T such that $100(\alpha)\%$ of the samples drawn from a population in which H_0 is true would yield a value of T that is as far from θ_0 as (or even farther from θ_0 than) that critical value, in the *hypothesized* direction. Then, if the researcher has (*before* looking at the data) hypothesized that $\theta > \theta_0$ (a mirror-image decision rule applies if the *a priori* hypothesis is that $\theta < \theta_0$),

If $|T^*|$ is $> cv_\alpha$ and $\hat{\theta}^*$ (the observed sample estimate of θ) $> \theta_0$ (i.e., the sample statistic came out on the predicted side of θ_0), accept H_1 that $\theta > \theta_0$.

If $|T^*|$ is $< cv_\alpha$ or $\hat{\theta}^* < \theta_0$ (i.e., either the sample estimate was on the nonpredicted side of θ_0 or the sample result, while in the hypothesized

direction, wasn't discrepant enough from θ_0 to yield statistical significance), fail to reject H_0 that $\theta \leq \theta_0$ (i.e., conclude that the data provide insufficient evidence to prove that the researcher's hypothesis is correct).

This decision rule can be illustrated for the same case (difference between two means) that was used to illustrate DR 3 as follows (Figure 3):

One-tailed or Unidirectional? The labeling of the two kinds of tests described above as 'one-tailed' and 'two-tailed' is a bit of a misnomer, in that the crucial logical characteristics of these tests are not a function of which tail(s) of the sampling distribution constitute the rejection region, but of the nature of the alternative hypotheses that can be accepted as a result of the tests. For instance, the difference between two means can be tested (via 'two-tailed' logic) at the 0.05 level by determining whether the square of t^* for the difference falls in the right-hand tail (i.e., beyond the 95th percentile) of the F distribution with one df for numerator and the same

df for denominator as the t Test's df. Squaring t^* has essentially folded both tails of the t distribution into a single tail of the F distribution. It's what one does after comparing your test statistic to its critical value, not how many tails of the sampling distribution of your chosen test statistic are involved in that determination, that determines whether you are conducting a 'two-tailed' significance test as presented in textbooks or a 'two-tailed' significance test as employed by sound researchers or a 'one-tailed' test. Perhaps it would be better to label the above two kinds of tests as *bidirectional* versus *unidirectional* tests.

The Unpalatable Choice Presented by Classical Significance Tests as Classically Presented. Now, look again at the conclusions that can be reached under the above two decision rules. Nary a hint of direction of effect appears in either of the two conclusions (θ could $= \theta_0$ or $\theta \neq \theta_0$ in the general case, μ_1 could $= \mu_2$ or $\mu_1 \neq \mu_2$ in the example) that could result from a two-tailed test.

Further, as hinted earlier, there are no true null hypotheses except by construction. No two populations have precisely identical means on any real variable; no treatment to which we can expose the members of any real population leaves them utterly unaffected; and so on. Thus, even a statistically significant two-tailed test provides no new information. Yes, we can be 95% confident that the true value of the population parameter doesn't precisely equal θ_0 to 45 or 50 decimal places – but, then, we were 100% confident of that before we ever looked at a single datum!

For the researcher who wishes to be able to come to a conclusion (at least for purposes of the discussion of this study's results) about the *sign* (direction) of the difference between θ and θ_0 , textbook-presented significance testing leaves only the choice of conducting a one-tailed test. Doing so, however, requires not only that she make an *a priori* prediction as to the direction of the effect being tested (i.e., as to the sign of $\theta - \theta_0$), but that she declare that hypothesis to be impervious to any empirical evidence to the contrary. (If we conduct a one-tailed test of the hypothesis that $\mu_1 > \mu_2$, we can never come to the conclusion that $\mu_1 < \mu_2$ no matter how much larger $\bar{Y}_1$ is than $\bar{Y}_2$ and no matter how close to negative infinity our t ratio for the difference gets.)

In my opinion, this may be a satisfying way to run a market test of your product ('We tested every

competitor's product against ours, and not a one performed statistically significantly better than our product' – because we did one-tailed tests, and we sure weren't going to predict better performance for the competitor's product), but in my opinion it's a terrible way to run a science.

In short, and to reiterate the second sentence of this entry, classical statistical inference as described in almost all textbooks forces the researcher who takes that description seriously to choose among affirming a truism, accepting a falsehood on scant evidence, or violating one of the most fundamental tenets of scientific method by declaring one's research hypothesis impervious to disconfirmation.

Fortunately, most researchers *don't* take the textbook description seriously. Rather, they conduct two-tailed tests, but with the three possible outcomes spelled out in DR 1 through DR 4 above. Or they pretend to conduct a one-tailed test but abandon that logic if the evidence is overwhelmingly in favor of an effect opposite in direction to their research hypothesis, thus effectively conducting a split-tailed test such as those described in the entry, *Classical Statistical Inference Extended: Split-tailed Tests* [9], but with a somewhat unconventional alpha level. (E.g., if you begin by planning a one-tailed test with $\alpha = 0.05$ but revert to a two-tailed test if t comes out large enough to be significant in the direction opposite to prediction by a 0.05-level two-tailed test, you are effectively conducting a split-tailed test with an alpha of 0.05 in the predicted direction and 0.025 in the nonpredicted direction, for a total alpha of 0.075. See [1] for an example of a research report in which exactly that procedure was followed.)

However, one does still find authors who explicitly state that you must conduct a one-tailed test if you have any hint about the direction of your effect (e.g., [13], p. 136); or an academic department that insists that intro sections of dissertations should state all hypotheses in null form, rather than indicating the direction in which you predict your treatment conditions will differ (see [15] and <http://www.blackwell-synergy.com/links/doi/10.1111/j.1365-2648.2004.03074.x/abs/;jsessionid=11twdxnTU-ze> for examples of this practice and <http://etleads.csuhayward.edu/6900.html> and http://www.edb.utexas.edu/coe/depts/sped/syllabi/Spring%2003'/Parker_sed387_2nd.htm for examples of dissertation guides that enshrine it); or an

article in which the statistical significance of an effect is reported, with no mention of the direction of that effect (see http://www.gerardkeegan.co.uk/glossary/gloss_repwrit.htm and <http://web.hku.hk/~rytyeung/nurs2509b.ppt> for examples in which this practice is held up as a model for students to follow); or a researcher who treats a huge difference opposite to prediction as a nonsignificant effect – just as textbook-presented logic dictates. (Lurking somewhere in, but as yet unrecovered from my 30+ years of notes is a reference to a specific study that committed that last-mentioned sin.)

There are even researchers who continue to champion one-tailed tests. As pointed out earlier, many of these (fortunately) do not really follow the logic of one-tailed tests. For instance, after expressing concern about and disagreement with this entry's condemnation of one-tailed tests, section editor Ranald Macdonald (email note to me) mentioned that, of course, should a study for which a one-tailed test had been planned yield a large difference opposite to prediction he would consider the assumptions of the test violated and acknowledge the reversal of the predicted effect – that is, the decision rule he applies is equivalent to a split-tailed test with a somewhat vague ratio of predicted to nonpredicted alpha. Others, though (e.g., Cohen, in the entry on **Directed Alternatives in Testing** and many of the references on ordinal alternatives cited in that entry) explicitly endorse the logic of one-tailed tests.

Two especially interesting examples are provided by Burke [4] and Lohnes & Cooley [13]. Burke, in an early salvo of the 1950s debate with Jones on one-tailed versus two-tailed tests (which Leventhal [12] reports was begun because of Burke's concern that some researchers were coming to directional conclusions on the basis of two-tailed tests) concedes that a two-tailed rejection region could be used to support the directional hypothesis that the experimental-condition μ is greater than the control-condition μ – but then goes on to say that if a researcher did so 'his position would be unenviable. For following the rules of (such a) test, he would have to reject the (null hypothesis) in favor of the alternative ($\mu_E > \mu_C$), even though an observed difference ($\bar{Y}_1 - \bar{Y}_2$) was a substantial negative value.' Such are the consequences of the assumption that any significance test can have only two outcomes, rather than three: If your alternative hypothesis is that $\mu_E > \mu_C$, that leaves only $H_0: \mu_E \leq \mu_C$ as the other possible conclusion.

Lohnes and Cooley [13] follow their strong endorsement of one-tailed tests by an even stronger endorsement of traditional, symmetric confidence intervals: 'The great value of (a CI) is that it dramatizes that *all* values of μ within these limits are tenable in the light of the available evidence.' However, those nonrejected values include every value that would be rejected by a one-tailed test but not by a two-tailed test. More generally, it is the set of values that would not be rejected by a two-tailed test that match up perfectly with the set of values that lie within the symmetric confidence interval. Lohnes and Cooley thus manage to strongly denigrate two-tailed tests and to strongly endorse the logically equivalent symmetric confidence-interval procedure within a three-page interval of their text.

Few researchers would disagree that it is eminently reasonable to temper the conclusions one reaches on the basis of a single study with the evidence available from earlier studies and/or from logical analysis. However, as I explain in the companion entry, one can use **split-tailed tests** (Braver [3], Kaiser [11]) to take prior evidence into account and thereby increase the power of your significance tests without rending your directional hypothesis disconfirmable – and while preserving, as the one-tailed test does not, some possibility of reaching the correct conclusion about the sign of the population parameter when you have picked the wrong directional hypothesis.

Classical Test Models

Classical test theory (CTT) covers a whole set of psychometric models and procedures whose main objective is to solve the basic problems arising in the measurement of variables in the social sciences. Thus, for example, when psychologists measure a variable such as intelligence or extraversion, to name but two examples, and obtain an empirical score, their interest lies not so much in the score itself as in the inferences and interpretations that can be made from it, with a view to gaining more knowledge about some aspect of a person's behavior. Of course, for these interpretations and inferences to have the appropriate foundation, we need accurate knowledge of the different psychometric properties of the instrument used. CTT permits the detailed description of the metric characteristics of the measurement instruments commonly used by social scientists and other social science professionals. This set of procedures is referred to as 'classical' because it has been firmly established for some 100 years, and is widely used by those working in the social sciences, especially in the fields of psychology and education, in which the majority of these procedures originated and were developed. In an alternative to this classical approach, there began to emerge in the 1960s other psychometric models in response to some problems that had not been dealt with adequately within the classical framework, and which are referred to under the general name of **Item Response Theory** (IRT). The two approaches are complementary, each one being employed according to the type of problem faced.

Brief Historical Note

The first developments in what we know today under the generic name of classical test theory are to be found in the pioneering work of **Spearman** [29–31]. Later, Guilford [14] published a text in which he tried to collate and organize all the work done so far. But it would be Gulliksen [15] who produced the key work in the field, in which he set down in a systematic way the basic contributions of CTT. It can indeed be claimed that by the time his book was published the essential basis of classical test theory was complete. The year 1954 saw the publication

of the first *Technical recommendations for psychological tests and diagnostic techniques*; since then, these guidelines, developed jointly by the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education, and which constitute an update of the psychometric consensus, have undergone several revisions, the most recent in 1999 [2]. Another essential text, and one which bridges the classical approach and the new psychometric models of IRT, is that of Lord and Novick [20]. This important work served both to reanalyze the classical approach and to provide a springboard for new item response theory models, which, as already pointed out, provided the solution to some of the problems for which the classical framework was inadequate. Other texts in which the reader can find clear and well-documented presentations of CTT are [21, 1, 35, 8, 23, 25, 26].

Below is a brief chronology showing some of the landmarks of CTT (Table 1), adapted from [25, 26]. It does not include the more recent developments within the paradigm of item response theory.

Classical Linear Model

The psychometric knowledge and techniques included within the generic term of 'classical test theory' derive from developments based on the linear model, which has its origins in the pioneering work of Spearman [29–31]. In this model, a person's empirical score from a test (X) is assumed to be made up of two additive components, the true score (T) that corresponds to the expected score on the test for the person (over multiple parallel tests), and a certain measurement error (e). Formally, the model can be expressed as:

$$X = T + e, \quad (1)$$

where X is the empirical score obtained, T is the true score and e is the measurement error.

In order to be able to derive the formulas necessary for calculating the reliability, the model requires three assumptions and a definition. It is assumed (a) that a person's true score in a test would be that obtained as an average if the test were applied an infinite number of times [$E(X) = T$], (b) that there is no correlation between person true score and measurement error ($\rho_{te} = 0$), and (c) that the

2 Classical Test Models

Table 1 Classical Psychometric Chronology

1904	Spearman publishes his two-factor theory of intelligence and the attenuation formulas E. L. Thorndike publishes the book <i>An Introduction to the Theory of Mental and Social Measurements</i> [34]
1905	Binet and Simon publish the first intelligence scale
1910	Spearman–Brown formula that relates reliability to the length of tests is published
1916	Terman publishes Stanford’s revision of the Binet–Simon scale
1918	Creation of the Army Alpha tests
1931	Thurstone publishes <i>The Reliability and Validity of Tests</i> [36]
1935	The Psychometric Society is founded Buros publishes his first review of tests (<i>Mental Measurements Yearbook</i>)
1936	Guilford publishes <i>Psychometric Methods</i> First issue of the journal <i>Psychometrika</i>
1937	Kuder and Richardson publish their formulas including KR_{20} and KR_{21}
1938	Bender, Raven, and PMA tests published
1939	Wechsler proposes his scale for measuring intelligence
1940	Appearance of the personality questionnaire <i>Minnesota Multiphasic Personality Inventory</i> (MMPI)
1946	Stevens proposes his four measurement scales: Nominal, ordinal, interval and ratio [33]
1948	Educational Testing Service (ETS) in the United States is established
1950	Gulliksen publishes <i>Theory of Mental Tests</i>
1951	Cronbach introduces coefficient Alpha [9] First edition of <i>Educational Measurement</i> is edited by Lindquist
1954	First edition of <i>Technical Recommendations for Psychological Tests and Diagnostic Techniques</i> is published
1955	Construct validity is introduced by Cronbach and Meehl [11]
1958	Torgerson publishes <i>Theory and Methods of Scaling</i> [37]
1959	Discriminant convergent validity is introduced by Campbell and Fiske [6]
1960	Rasch proposes the one-parameter logistic model better known as the Rasch model
1963	Criterion-referenced testing is introduced by Robert Glaser [13] Generalizability theory is introduced by Lee Cronbach
1966	Second edition of <i>Standards for Educational and Psychological Tests</i> is published
1968	Lord and Novick publish <i>Statistical Theories of Mental Tests Scores</i>
1971	Second edition of <i>Educational Measurement</i> is published, edited by Robert Thorndike
1974	Third edition of <i>Standards for Educational and Psychological Tests</i> is published
1980	Lord publishes <i>Applications of Item Response Theory to Practical Testing Problems</i>
1985	Fourth edition of <i>Standards for Educational and Psychological Tests</i> is published Hambleton and Swaminathan’s book, <i>Item Response Theory: Principles and Applications</i> , is published
1989	The third edition of <i>Educational Measurement</i> , edited by Robert Linn, is published
1997	Seventh edition of Anastasi’s <i>Psychological Testing</i> is published [3] <i>Handbook of Modern IRT Models</i> by van der Linden and Hambleton [38] is published
1999	Fifth edition of <i>Standards for Educational and Psychological Tests</i> is published

measurement errors from parallel forms are not correlated. Moreover, parallel tests are defined as those that measure the same construct, and in which a person has the same true score on each one, and the standard error of measurement (the standard deviation of the error scores) is also identical across parallel forms.

From this model, by means of the corresponding developments, it will be possible to arrive at operational formulas for the estimation of the errors (e) and true scores (T) of persons. These deductions constitute the essence of CTT, whose formulation is described in the classic texts already mentioned.

Reliability

Through the corresponding developments, we obtain the formula of the *reliability coefficient* ($\rho_{xx'}$) (see **Reliability: Definitions and Estimation**). Its formula expresses the amount of variance of true measurement (σ_T^2) there is in the empirical measurement (σ_x^2). This formula, which is purely conceptual, cannot be used for the empirical calculation of the reliability coefficient value. This calculation is carried out using three main designs: (a) the correlation between two parallel forms of the test, (b) the correlation between two

random halves of the test corrected using the Spearman–Brown formula, and (c) the correlation between two applications of the same test to a sample of persons. Each one of these procedures has its pros and cons, and suits some situations better than others. In all cases, the value obtained (reliability coefficient) is a numerical value between 0 and 1, indicating, as it approaches 1, that the test is measuring consistently. In the psychometric literature, there are numerous classic formulas for obtaining the empirical value of the reliability coefficient, some of the most important being those of Rulon [28], Guttman [16], Flanagan [12], the KR_{20} and KR_{21} [19], or the popular coefficient alpha [9], which express the reliability of the test according to its internal consistency.

Regardless of the formula used for calculating the reliability coefficient, what is most important is that all measurements have an associated degree of accuracy that is empirically calculable. The commonest sources of error in psychological measurement have been widely studied by specialists, who have made detailed classifications of them [32]. In general, it can be said that the three most important sources of error in psychological measurement are: (a) *the assessed persons themselves*, who come to the test in a certain mood, with certain attitudes and fears, and levels of anxiety in relation to the test, or affected by any kind of event prior to the assessment, all of which can influence the measurement errors, (b) *the measurement instrument* used, and whose specific characteristics can differentially affect those assessed, and (c) *the application, scoring, and interpretation* by the professionals involved [24].

Validity

From persons' scores, a variety of inferences can be drawn, and validating the test consists in checking empirically that the inferences made based on the test are correct (*see Validity Theory and Applications*). It could therefore be said that, strictly speaking, it is not the test that is validated, but rather the inferences made on the basis of the test. The procedure followed for validating these inferences is the one commonly used by scientists, that is, defining working hypotheses and testing them empirically. Thus, from a methodological point of view, the validation process for a test does not differ in essence from customary scientific methodology. Nevertheless, in this specific

context of test validation, there have been highly effective and fruitful forms of collecting empirical evidence for validating tests, and which, classically, are referred to as: *Content validity*, *predictive validity*, and *construct validity*. These are not three forms of validity – there is only one – but rather three common forms of obtaining data in the validation process. Content validity refers to the need for the content of the test to adequately represent the construct assessed. Predictive validity indicates the extent to which the scores in the test predict a criterion of interest; it is operationalized by means of the correlation between the test and the criterion, which is called the validity coefficient (ρ_{xy}). Construct validity [11] refers to the need to ensure that the assessed construct has entity and consistency, and is not merely spurious. There are diverse strategies for evaluating construct validity. Thus, for example, when we use the technique of **factor analysis** (or, more generally, **structural equation modeling**), we refer to factorial validity. If, on the other hand, we use the data of a multitrait-multimethod matrix (*see Multitrait–Multimethod Analyses*), we talk of convergent-discriminant validity. Currently, the concept of validity has become more comprehensive and unitary, with some authors even proposing that the consequences of test use be included in the validation process [2, 22].

Extensions of Classical Test Theory

As pointed out above, the classical linear model permits estimation of the measurement errors, but not their source; this is presumed unknown, and the errors randomly distributed. Some models within the classical framework have undertaken to break down the error, and, thus, offer not only the global reliability but also its quantity as a function of the sources of error. The most well known model is that of *generalizability theory*, proposed by Cronbach and his collaborators [10]. This model allows us to make estimations about the size of the different error sources. The reliability coefficient obtained is referred to as the generalizability coefficient, and indicates the extent to which a measurement is generalizable to the population of measurements involved in the measurement (*see Generalizability Theory: Basics*). A detailed explanation of generalizability theory can be found in [5].

The tests mentioned up to now are those most commonly used in the field of psychology for assessing constructs such as intelligence, extraversion or neuroticism. They are generally referred to as *normative tests*, since the scores of the persons assessed are expressed according to the norms developed in a normative group. A person's score is expressed according to the position he or she occupies in the group, for example, by means of centiles or standard scores. However, in educational and professional contexts, it is often of more interest to know the degree to which people have mastery in a particular field than their relative position in a group of examinees. In this case, we talk about criterion-referenced tests [13, 17] for referring to tests whose central objective is to assess a person's ability in a field, domain, or criterion (*see Criterion-Referenced Assessment*). In these circumstances, the score is expressed not according to the group, but rather as an indicator of the extent of the person's ability in the area of interest. However, the classical reliability coefficients of normative tests are not particularly appropriate for this type of test, for which we need to estimate other indicators based on the reliability of classifications [4]. Another specific technical problem with criterion-referenced tests is that of setting cut-off points for discriminating between those with mastery in the field and those without. A good description of the techniques available for setting cut-off points can be found in [7].

Limitations of the Classical Test Theory Approach

The classical approach is still today commonly used in constructing and analyzing psychological and educational tests [27]. The reasons for this widespread use are basically its relative simplicity, which makes it easy to understand for the majority of users, and the fact that it works well and can be adapted to the majority of everyday situations faced by professionals and researchers. These are precisely its strong points. Nevertheless, in certain assessment situations, the new psychometric models derived from item response theory have many advantages over the classical approach [18]. More about the limitations of CTT are found in (*see Item Response Theory (IRT) Models for Dichotomous Data*). It is fair to point out that

workers using the classical approach have developed diverse statistical strategies for the appropriate solutions of many of the problems that surface in practice, but the more elegant and technically satisfactory solutions are provided by item response models.

Classical Test Score Equating

Introduction

Educational and psychological tests often are developed with *alternate forms* that contain different sets of test questions. The alternate forms are administered on different occasions. To enhance the security of the tests and to allow examinees to be tested more than once, alternate forms are administered on different occasions. *Test content specifications* detail the number of questions on a test from each of a number of content areas. *Test statistical specifications* detail the statistical properties (e.g., difficulty) of the test questions. Alternate forms of tests are built to the same content and statistical specifications, which is intended to lead to alternate forms that are very similar in content and statistical properties.

Although alternate forms are built to be similar, they typically differ somewhat in difficulty. *Test equating* methods are statistical methods used to adjust test scores for the differences in test difficulty among the forms. To appropriately apply test equating methodology, the alternate forms must be built to the same content and statistical specifications. Equating methods adjust for small differences in test difficulty among the forms. As emphasized by Kolen and Brennan [5], p. 3, '*equating adjusts for differences in difficulty, not for differences in content*'. The goal of equating is to enable scores on the alternate test forms to be used interchangeably. Test equating is used when alternate forms of a test exist, and examinees who are administered the different test forms are considered for the same decision.

The implementation of test equating requires a process for collecting data, referred to as an *equating design*. A variety of equating designs exist. Some of the more popular ones are considered here. Statistical *equating methods* are also a component of the equating process. Traditional and **item response theory (IRT)** statistical methods exist. Only the traditional methods are considered in this entry.

Test equating has been conducted since the early twentieth century. The first comprehensive

treatment of equating was presented by Flanagan [3]. Subsequent treatments by Angoff [2], Holland and Rubin [4], Petersen, Kolen, and Hoover [7], Kolen and Brennan [5, 6], and von Davier, Holland, and Thayer [8] trace many of the developments in the field. AERA/APA/NCME [1] provides standards that are to be met when equating tests in practice.

The Scaling and Equating Process

Raw scores on tests often are computed as the number of test questions that a person answers correctly. Other types of raw scores exist, such as scores that are corrected for guessing, and scores on written essays that are scored by judges. Raw scores typically are transformed to *scale scores*. Scale scores are used to facilitate score interpretation ([7], [5]). Often, properties of score scales are set with reference to a particular population. The score scale can be established using an initial alternate form of a test. Raw scores on a subsequent alternate form are equated to raw scores on this initial form. The raw-to-scale score transformation for the initial form is then applied to the equated scores on the subsequent form. Later, raw scores on new forms are equated to previously equated forms and then transformed to scale scores. The scaling and equating process leads to scores from all forms being reported on a common scale. The intent of this process is to be able to say, for example, that 'a scale score of 26 indicates the same level of proficiency whether it is earned on Form X, Form Y, or Form Z'.

Equating Designs

Equating requires that data be collected and analyzed. Various data collection designs are used to conduct equating. Some of the most common designs are discussed in this section. In discussing each of these designs, assume that Form X is a new form. Also assume that Form Y is an old form, for which a transformation of raw-to-scale scores already has been developed. The equating process is intended to relate raw scores on Form X to raw scores on Form Y and to scale scores.

2 Classical Test Score Equating

Random Groups

In the *random groups design*, alternate test forms are randomly assigned to examinees. One way to implement the random groups design is to package the test booklets so that the forms alternate. For example, if two test forms, Form X and Form Y, are to be included in an equating study, Form X and Form Y test booklets would be alternated in the packages. When the forms are distributed to examinees, the first examinee would receive a Form X test booklet, the second examinee a Form Y booklet, and so on. This assignment process leads to comparable, *randomly equivalent groups*, being administered Form X and Form Y.

Assuming that the random groups are fairly large, differences between raw score means on Form X and Form Y can be attributed to differences in difficulty of the two forms. Suppose, for example, following a random group data collection, the mean raw score for Form X is 70 and the mean raw score for Form Y is 75. These results suggest that Form X is 5 raw score points more difficult than Form Y. This conclusion is justified because the group of examinees taking Form X is randomly equivalent to the group of examinees taking Form Y.

Single Group Design

In the *single group design*, the same examinees are administered two alternate forms. The forms are separately timed. The order of the test forms is usually counterbalanced. One random half of the examinees is administered Form X followed by Form Y. The other random half is administered Form Y followed by Form X. Counterbalancing is used to control for context effects, such as practice or fatigue. Counterbalancing requires the assumption that the effect of taking Form X prior to Form Y has the same effect as taking Form Y prior to Form X. If this assumption does not hold, then *differential order effects* are said to be present, and the data on the form taken second are discarded, resulting in a considerable loss of data.

Common-item Nonequivalent Groups

In the *common-item nonequivalent groups design*, Form X and Form Y are administered to different (nonequivalent) groups of examinees. The two forms

have items in common. Two variants of this design exist. When using an *internal set of common items*, the common items contribute to the examinee's score on the form. With an internal set, typically, the common items are interspersed with the other items on the test. When using an *external set of common items*, the common items do not contribute to the examinee's score on the form taken. With an external set, the common items typically appear in a separately timed section.

When using the common-item nonequivalent groups design, the common items are used to indicate how different the group of examinees administered Form X is from the group of examinees administered Form Y. Strong statistical assumptions are used to translate the differences between the two groups of examinees on the common items to differences between the two groups on the complete forms.

Because scores on the common items are used to indicate differences between the examinee groups, it is important that the common items fully represent the content of the test forms. Otherwise, a misleading picture of group differences is provided. In addition, it is important that the common items behave in the same manner when they are administered with Form X as with Form Y. So, the common items should be administered in similar positions in the test booklets in the two forms, and the text of the common items should be identical.

Comparison of Equating Designs

The benefits and limitations of the three designs can be compared in terms of ease of test development, ease of administration, security of test administration, strength of statistical assumptions, and sample size requirements. Of the designs considered, the common-item nonequivalent groups design requires the most complex test development process. Common-item sections must be developed that mirror the content of the total test so that the score on the common-item sections can be used to give an accurate reflection of the difference between the group of examinees administered the old form and the group of examinees administered the new form. Test development is less complex for the random groups and single group designs, because there is no need to construct common-item sections.

However, the common-item nonequivalent groups design is the easiest of the three designs to administer.

Only one test form needs to be administered on each test date. For the random groups design, multiple forms must be administered on a test date. For the single group design, each examinee must take two forms, which typically cannot be done in a regular test administration.

The common-item nonequivalent design tends to lead to greater test security than the other designs, because only one form needs to be administered at a given test date. With the random groups and single group designs, multiple forms are administered at a particular test date to conduct equating. However, security issues can be of concern with the common-item nonequivalent groups design, because the common items must be repeatedly administered.

The common-item nonequivalent groups design requires the strongest statistical assumptions. The random groups design requires only weak assumptions, mainly that the random assignment process was successful. The single group design requires stronger assumptions than the random groups design, in that it assumes no differential order effects.

The random groups design requires the largest sample sizes of the three designs. Assuming no differential order effects, the single group design has the smallest sample size requirements of the three designs because, effectively, each examinee serves as his or her own control.

As is evident from the preceding discussion, each of the designs has strengths and weaknesses. The choice of design depends on weighing the strengths and weaknesses with regard to the testing program under consideration. Each of these designs has been used to conduct equating in a variety of testing programs.

Statistical Methods

Equating requires that a relationship between alternate forms be estimated. Equating methods result in a transformation of scores on the alternate forms so that the scores possess specified properties. For traditional equating methods, transformations of scores are found such that for the alternate forms, after equating, the distributions, or central moments of the distributions, are the same in a population of examinees for the forms to be equated.

Traditional observed score equating methods define score correspondence on alternate forms by

setting certain characteristics of score distributions equal for a specified population of examinees. In traditional *equipercentile equating*, a transformation is found such that, after equating, scores on alternate forms have the same distribution in a specified population of examinees. Assume that scores on Form X are to be equated to the raw score scale of Form Y. Define X as the random variable score on Form X, Y as the random variable score on Form Y, F as the cumulative distribution function of X in the population, and G as the cumulative distribution function of Y in the population. Let e_Y be a function that is used to transform scores on Form X to the Form Y raw score scale, and let G^* be the cumulative distribution function of e_Y in the same population. The function e_Y is defined to be the equipercentile equating function in the population if

$$G^* = G. \quad (1)$$

Scores on Form X can be transformed to the Form Y scale using equipercentile equating by taking,

$$e_Y(x) = G^{-1}[F(x)], \quad (2)$$

where x is a particular value of X , and G^{-1} is the inverse of the cumulative distribution function G .

Finding equipercentile equivalents would be straightforward if the distributions of scores were continuous. However, test scores typically are discrete (e.g., number of items correctly answered). To conduct equipercentile equating with discrete scores, the percentile rank of a score on Form X is found for a population of examinees. The equipercentile equivalent of this score is defined as the score on Form Y that has the same percentile rank in the population. Owing to the discreteness of scores, the resulting equated score distributions are only approximately equal.

Because many parameters need to be estimated in equipercentile equating (percentile ranks at each Form X and Form Y score), equipercentile equating is subject to much sampling error. For this reason, smoothing methods are often used to reduce sampling error. In *presmoothing methods*, the score distributions are smoothed. In *posts smoothing methods*, the equipercentile function is smoothed. Kolen and Brennan [5] discussed a variety of smoothing methods. von Davier, Holland, and Thayer [8] presented a comprehensive set of procedures, referred to as **kernel smoothing**, that incorporates procedures for

presmoothing score distributions, handling the discreteness of test score distributions, and estimating standard errors of equating.

Other traditional methods are sometimes used that can be viewed as special cases of the equipercentile method. In *linear equating*, a transformation is found that results in scores on Form X having the same mean and standard deviation as scores on Form Y. Defining $\mu(X)$ as the mean score on Form X, $\sigma(X)$ as the standard deviation of Form X scores, $\mu(Y)$ as the mean score on Form Y, $\sigma(Y)$ as the standard deviation of Form Y scores, and l_Y as the linear equating function,

$$l_Y(x) = \sigma(Y) \left[\frac{x - \mu(X)}{\sigma(X)} \right] + \mu(Y). \quad (3)$$

Unless the shapes of the score distributions for Form X and Form Y are identical, linear and equipercentile methods produce different results. However, even when the shapes of the distributions differ, equipercentile and linear methods produce similar results near the mean. When interest is in scores near the mean, linear equating often is sufficient. However, when interest is in scores all along the score scale and the sample size is large, then equipercentile equating is often preferable to linear equating.

For the random groups and single group designs, the sample data typically are viewed as representative of the population of interest, and the estimation of the traditional equating functions proceeds without needing to make strong statistical assumptions. However, estimation in the common-item nonequivalent groups design requires strong statistical assumptions. First, a population must be specified in order to define the equipercentile or linear equating relationship. Since Form X is administered to examinees from a different population than is Form Y, the population used to define the equating relationship typically is viewed as a combination of these two populations. The combined population is referred to as the *synthetic population*. Three common ways to define the synthetic population are to equally weight the population from which the examinees are sampled to take Form X and Form Y, weight the two populations by their respective sample sizes, or define the synthetic population as the population from which examinees are sampled to take Form X. It turns out that the definition of the synthetic population typically has little effect on the final equating results. Still, it is necessary to define a synthetic population

in order to proceed with traditional equating with this design.

Kolen and Brennan [5] described a few different equating methods for the common-item nonequivalent groups design. The methods differ in terms of their statistical assumptions. Define V as score on the common items. In the Tucker linear method, the linear regression of X on V is assumed to be the same for examinees taking Form X and the examinees taking Form Y. A similar assumption is made about the linear regression of Y on V . In the Levine linear observed score method, similar assumptions are made about true scores, rather than observed scores. No method exists to directly test all of the assumptions that are made using data that are collected for equating. Methods also exist for equipercentile equating under this design that make somewhat different regression assumptions.

Equating Error

Minimizing equating error is a major goal when developing tests that are to be equated, designing equating studies, and conducting equating. *Random equating error* is present whenever samples from populations of examinees are used to estimate equating relationships. Random error depends on the design used for data collection, the score point of interest, the method used to estimate equivalents, and the sample size. Standard errors of equating are used to index random error. Standard error equations have been developed to estimate standard errors for most designs and methods, and resampling methods like the **bootstrap** can also be used. In general, standard errors diminish as sample size increases. Standard errors of equating can be used to estimate required sample sizes for equating, for comparing the precision of various designs and methods, and for documenting the amount of random error in equating.

Systematic equating error results from violations of assumptions of the particular equating method used. For example, in the common-item nonequivalent groups design, systematic error will result if the Tucker method is applied and the regression-based assumptions that are made are not satisfied. Systematic error typically cannot be quantified in operational equating situations.

Equating error of both types needs to be controlled because it can propagate over equatings and result

in scores on later test forms not being comparable to scores on earlier forms. Choosing a large enough sample size given the design is the best way to control random error. To control systematic error, the test must be constructed and the equating implemented so as to minimize systematic error. For example, the assumptions for any of the methods for the common-item nonequivalent groups design tend to hold better when the groups being administered the old and the new form do not differ too much from each other. The assumptions also tend to hold better when the forms to be equated are very similar to one another, and when the content and statistical characteristics of the common items closely represent the content and statistical characteristics of the total test forms. One other way to help control error is to use what is often referred to as *double-linking*. In double-linking, a new form is equated to two previously equated forms. The results for the two equatings often are averaged to produce a more stable equating than if only one previously equated form had been used. Double-linking also provides for a built-in check on the adequacy of the equating.

Selected Practical Issues

Owing to practical constraints, equating cannot be used in some situations where its use might be desirable. Use of any of the equating methods requires test security. In the single group and random groups design, two or more test forms must be administered in a single test administration. If these forms become known to future examinees, then the equating and the entire testing program could be jeopardized. With the common-item nonequivalent groups design, the common items are administered on multiple test dates. If the common items become known to examinees, the equating also is jeopardized. In addition, equating requires that detailed content and statistical test specifications be used to develop the alternate forms. Such specifications are a prerequisite to conducting adequate equating.

Although the focus of this entry has been on equating multiple-choice tests that are scored number-correct, equating often can be used with tests that are scored in other ways such as essay tests scored by human raters. The major problem with equating

such tests is that, frequently, very few essay questions can be administered in a reasonable time frame, which can lead to concern about the comparability of the content from one test form to another. It also might be difficult, or impossible, when the common-item nonequivalent groups design is used to construct common-item sections that represent the content of the complete tests.

Concluding Comments

Test form equating has as its goal to use scores from alternate test forms interchangeably. Test development procedures that have detailed content and statistical specifications allow for the development of alternate test forms that are similar to one another. These test specifications are a necessary prerequisite to the application of equating methods.

Classification and Regression Trees

There are a variety of regression type models, for example, **multiple linear regression**, **generalized linear models**, **generalized linear mixed effects models**, **generalized additive models** and **nonlinear models**. These models are widely used, but they may not give faithful data descriptions when the assumptions on which they are based are not met, or in the presence of higher-order interactions among some of the explanatory variables. An alternative approach, classification and regression trees (CART), has evolved to overcome some of these potential problems with the more usual types of regression models. The central idea of the CART procedure is the formation of subgroups of individuals within which the response variable is relatively homogeneous. Interpretation in terms of prognostic group identification is frequently possible.

Tree-based Models

Developing a tree model involves the construction of a collection of rules that eventually lead to the terminal nodes. An example of a rule for data consisting of a response variable y and a set of explanatory variables, $x_1, \dots, x_p$, might be if $(x_2 < 410)$ and $(x_4 \in \{C, D, E\})$ and $(x_5 > 10)$ then the predicted value of y is 4.75 (if y is continuous), or, the probability that $y = 1$ is 0.7, if y is binary.

The complete collection of rules that defines the tree is arrived at by a process known as *recursive partitioning*. The essential steps behind this procedure are as follows:

- A series of binary splits is made based on the answers to questions of the type, ‘Is observation or case $i \in A$ ’, where A is a region of the covariate space.
- Answering such a question induces a partition, or split, of the covariate space; cases for which the answer is yes are assigned to one group, and those for which the answer is no to an alternative group.
- Most implementations of tree-modelling proceed by imposing the following constraints.

1. Each split depends on the value of only a single covariate.
 2. For ordered (continuous or categorical) covariates x_j , only splits resulting from questions of the form ‘Is $x_j < C$?’ are considered. Thus, ordering is preserved.
 3. For categorical explanatory variables, all possible splits into disjoint subsets of the categories are allowed.
- A tree is grown as follows:
 1. Examine every allowable split on each explanatory variable.
 2. Select and execute (i.e., create left and right ‘daughter’ nodes) from the best of these splits.
 - The initial or root node of the tree comprises the whole sample. Steps (1) and (2) above are then reapplied to each of the daughter nodes. Various procedures are used to control tree size, as we shall describe later.
 - To determine the best node to split into left and right daughter nodes at any stage in the construction of the tree, involves the use of a numerical *split function* $\phi(s, g)$; this can be evaluated for any split s of node g . The form of $\phi(s, g)$ depends on whether the response variable is continuous or categorical. For a continuous response variable the normal split function is based on the within-node sum of squares, that is, for a node g with N_g cases, the term

$$SS(g) = \sum_{i \in g} [y_i - \bar{y}(g)]^2 \quad (1)$$

where y_i denotes the response variable value for the i th individual and $\bar{y}(g)$ is the mean of the responses of the N_g cases in node g . If a particular split, s , of node g is into left and right daughter nodes, g_L and g_R then the least squares split function is

$$\phi(s, g) = SS(g) - SS(g_L) - SS(g_R) \quad (2)$$

and the best split of node g is determined as the one that corresponds to the maximum of (2) amongst all allowable splits.

For a categorical response variable (in particular, binary variables) split functions are based on trying to make the probability of a particular category of the

2 Classification and Regression Trees

variable close to one or zero in each node. Most commonly used is a log-likelihood function (see **Maximum Likelihood Estimation**) defined for node g as

$$LL(g) = -2 \sum_{i \in g} \sum_{k=1}^K y_{ik} \log(p_{gk}) \quad (3)$$

where K is the number of categories of the response variable, y_{ik} is an indicator variable taking the value 1 if individual i is in category k of the response and zero otherwise, and p_{gk} is the probability of being in the k th category of the response in node g , estimated as n_{gk}/N_g where n_{gk} is the number of individuals in category k in node g . The corresponding split function $\phi(s, g)$ is then simply

$$\phi(s, g) = LL(g) - LL(g_L) - LL(g_k) \quad (4)$$

and again the chosen split is that maximizing $\phi(s, g)$. (The split function $\phi(s, g)$ is often referred to simply as *deviance*.)

Trees are grown by recursively splitting nodes to maximize ϕ , leading to smaller and smaller nodes of progressively increased homogeneity. A critical question is ‘when should tree construction end and terminal nodes be declared?’ Two simple ‘stopping’ rules are as follows:

- *Node size-stop* when this drops below a threshold value, for example, when $N_g < 10$.
- *Node homogeneity* – stop when a node is homogeneous enough, for example, when its deviance is less than 1% of the deviance of the root node.

Neither of these is particularly attractive because they have to be judged relative to preset thresholds, misspecification of which can result in overfitting or underfitting. An alternative more complex approach is to use what is known as a *pruning algorithm*. This involves growing a very large initial tree to capture all potentially important splits, and then collapsing this backup using what is known as *cost complexity pruning* to create a nested sequence of trees.

Cost complexity pruning is a procedure which snips off the least important splits in the initial tree, where importance is judged by a measure of within-node homogeneity or *cost*. For a continuous variable, for example, cost would simply be the sum of squares term defined in (5.1). The cost of the entire tree, G , is then defined as

$$\text{Cost}(G) = \sum_{g \in \tilde{G}} SS(g) \quad (5)$$

where $\tilde{G}$ is the collection of terminal nodes of G . Next we define the complexity of G as the number of its terminal nodes, say $N_{\tilde{G}}$, and finally, we can define the cost-complexity of G as

$$CC_{\alpha}(G) = \text{Cost}(G) + \alpha N_{\tilde{G}} \quad (6)$$

where $\alpha \geq 0$ is called the *complexity parameter*. The aim is to minimize simultaneously both cost and complexity; large trees will have small cost but high complexity with the reverse being the case for small trees. Solely minimizing cost will err on the side of overfitting; for example, with $SS(g)$ we can achieve zero cost by splitting to a point where each terminal node contains only a single observation. In practice we use (6) by considering a range of values of α and for each find the subtree $G(\alpha)$ of our initial tree that minimizes $CC_{\alpha}(G)$. If α is small $G(\alpha)$ will be large, and as α increases, $N_{\tilde{G}}$ decreases. For a sufficiently large α , $N_{\tilde{G}} = 1$.

In this way, we are led to a sequence of possible trees and need to consider how to select the best. There are two possibilities:

- If a separate validation sample is available, we can predict on that set of observations and calculate the deviance versus α for the pruned trees. This will often have a minimum, and so the smallest tree whose sum of squares is close to the minimum can be chosen.
- If no validation set is available, one can be constructed from the observations used in constructing the tree, by splitting the observations into a number of (roughly) equally sized subsets. If n subsets are formed this way, $n - 1$ can be used to grow the tree and it can be tested on the remaining subset. This can be done n ways, and the results averaged.

Full details are available in Breiman et al. [1]

An Example of the Application of the CART Procedure

As an example of the application of tree-based models in a particular area we shall use data on the birthweight of babies given in Hosmer [2]. Birthweight of babies is often a useful indicator of how they will thrive in the first few months of their life. Low birthweight, say below 2.5 kg, is often a cause of concern for their welfare. The part of the data

Figure 1 Regression tree to predict birthweight from race and smoking status

with which we will be concerned is that involving the actual birthweight and two explanatory variables, *race* (white/black/other) and *smoke*, a binary variable indicating whether or not the mother was a smoker during pregnancy.

The regression tree for the data can be constructed using suitable software (for example, the `tree` function in S-PLUS (see **Software for Statistical Analyses**) and the tree is displayed graphically in Figure 1. Here, the first split is on race into white and black/other. Each of the new nodes is then further split on the smoke variable into smokers and nonsmokers, and then, in the left-hand side of the tree, further nodes are introduced by splitting race into black and other. The six terminal nodes and their average birthweights are as follows:

1. black, smokers: 2504, $n = 10$;
2. other, smokers: 2757, $n = 12$;
3. other, nonsmokers: 2816, $n = 55$;

4. black, nonsmokers: 2854, $n = 16$;
5. white, smokers: 2827, $n = 52$;
6. white, nonsmokers: 3429, $n = 44$.

Here, there is evidence of a race $\times$ smoke interaction, at least for black and other women. Among smokers, black women produce babies with lower average birthweight than do 'other' women. But for nonsmokers the reverse is the case.

Clinical Psychology

Quantitative sophistication is increasingly central to research in clinical psychology. Both our theories and the statistical techniques available to test our hypotheses have grown in complexity over the last few decades, such that the novice clinical researcher now faces a bewildering array of analytic options. The purpose of this article is to provide a conceptual overview of the use of statistics in clinical science. The first portion of this article describes five major research questions that clinical psychology researchers commonly address and provides a brief overview of the statistical methods that frequently are employed to address each class of questions. These questions are neither exhaustive nor mutually exclusive, but rather are intended to serve as a heuristic for organizing and thinking about classes of research questions in clinical psychology and the techniques most closely associated with them. The second portion of the article articulates guiding principles that underlie the responsible use of statistics in clinical psychology.

Five Classes of Research Questions in Clinical Psychology

Defining and Measuring Constructs

Careful attention to the definition and measurement of constructs is the bread and butter of clinical research. Constructs refer to abstract psychological entities and phenomena such as depression, marital violence, genetic influences, attention to negative information, acculturation, and cognitive-behavioral therapy (CBT). We specify these unobserved variables (*see* **Latent Variable**), as well as their interrelationships, in a theoretical model (e.g., CBT might be assumed to decrease depression in one's partner, which then decreases the likelihood of marital violence in the relationship). Our measurement model (*see* **Measurement: Overview**) specifies the way in which we operationally define the constructs of interest (e.g., our 'measurement variable', or 'indicator variable', for the construct of depression might be patient scores on the Beck Depression Inventory (BDI) [4]). Finally, our analytical model refers to the

way in which we statistically evaluate the hypothesized relationships between our measured variables (e.g., we might use **structural-equation modeling** (SEM), **analysis of variance** (ANOVA), or **logistic regression**). Later in this article, we discuss the importance of the consistency between these three models for making valid inferences about a theoretical model, as well as the importance of 'starting at the top' (i.e., the importance of theory for the rapid advancement of clinical research). Readers are urged to consult McFall and Townsend [36] for a more comprehensive overview of the specification and evaluation of the multiple layers of scientific models in clinical research.

Deciding how best to measure our constructs – that is, specifying the measurement model for the theoretical model of interest – is a critical first step in every clinical research project. Sometimes this step entails a challenging process of thinking logically and theoretically about how best to assess a particular construct. Consider, for example, the difficulty in defining what 'counts' as a suicide attempt. Is any dangerous personal action 'suicidal' (e.g., driving recklessly, jumping from high places, mixing barbiturates and alcohol)? Does the person have to report intending to kill herself, or are others' perceptions of her intention enough? How should intention be assessed in the very young or the developmentally delayed? Does the exhibited behavior have to be immediately life-threatening? What about life-threatening parasuicidal behaviors? Similar difficulties arise in attempting to decide how to assess physical child abuse, cognitive therapy, or an episode of overeating. These examples are intended to highlight the importance of recognizing that all phenomena of interest to clinical researchers are constructs. As a result, theoretical models of a construct and the chosen measurement models always should be distinguished – not collapsed and treated as one and the same thing – and the fit between theoretical and measurement models should be maximized.

More commonly, defining and measuring constructs entails scale development, in which researchers (a) create a set of items that are believed to assess the phenomenon or construct; (b) obtain many participants' responses to these items; and (c) use factor-analytic techniques (*see* **History of Factor Analysis: A Psychological Perspective**) to reduce the complexity of the numerous items to a much

smaller subset of theoretically interpretable constructs, which commonly are referred to as ‘factors’ or ‘latent variables’. For example, Walden, Harris, and Catron [53] used factor analysis when developing ‘How I Feel’, a measure on which children report the frequency and intensity of five emotions (happy, sad, mad, excited, and scared), as well as how well they can control these emotions. The authors generated 30 relevant items (e.g., the extent to which children were ‘scared almost all the time’ during the past three months) and then asked a large number of children to respond to them. **Exploratory factor analyses** of the data indicated that three underlying factors, or constructs, accounted for much of the variability in children’s responses: Positive Emotion, Negative Emotion, and Control. For example, the unobserved Negative Emotion factor accounted particularly well for variability in children’s responses to the sample item above (i.e., this item showed a large factor loading on the Negative Emotion factor, and small factor loadings on the remaining two factors). One particularly useful upshot of conducting a factor analysis is that it produces **factor scores**, which index a participant’s score on each of the underlying latent variables (e.g., a child who experiences chronic sadness over which she feels little control presumably would obtain a high score on the Negative Emotion factor and a lot score on the Control factor). Quantifying factor scores remains a controversial enterprise, however, and researchers who use this technique should understand the relevant issues [20]. Both Reise, Waller, and Comrey [44] and Fabrigar, Wegener, MacCallum, and Strahan [19] provide excellent overviews of the major decisions that clinical researchers must make when using exploratory factor-analytic techniques.

Increasingly, clinical researchers are making use of **confirmatory factor-analytic** techniques when defining and measuring constructs. Confirmatory approaches require researchers to specify both the number of factors and which items load on which factors *prior* to inspection and analysis of the data. Exploratory factor-analytic techniques, on the other hand, allow researchers to base these decisions in large part on what the data indicate are the best answers. Although it may seem preferable to let the data speak for themselves, the exploratory approach capitalizes on sampling variability in the data, and the resulting factor structures may be less likely to cross-validate (i.e., to hold up well in new samples

of data). Thus, when your theoretical expectations are sufficiently strong to place *a priori* constraints on the analysis, it typically is preferable to use the confirmatory approach to evaluate the fit of your theoretical model to the data. Walden et al. [53] followed up the exploratory factor analysis described above by using confirmatory factor analysis to demonstrate the validity and temporal stability of the factor structure for ‘How I Feel’.

Clinical researchers also use **item response theory**, often in conjunction with factor-analytic approaches, to assist in the definition and measurement of constructs [17]. A detailed description of this approach is beyond the scope of this article, but it is helpful to note that this technique highlights the importance of inspecting item-specific measurement properties, such as their difficulty level and their differential functioning as indicators of the construct of interest. For clinical examples of the application of this technique, see [27] and [30].

Cluster analysis is an approach to construct definition and measurement that is closely allied to factor analysis but exhibits one key difference. Whereas factor analysis uncovers unobserved ‘factors’ on the basis of the similarity of variables, cluster analysis uncovers unobserved ‘typologies’ on the basis of the similarity of people. Cluster analysis entails (a) selecting a set of variables that are assumed to be relevant for distinguishing members of the different typologies; (b) obtaining many participants’ responses to these variables; and (c) using cluster-analytic techniques to reduce the complexity among the numerous participants to a much smaller subset of theoretically interpretable typologies, which commonly are referred to as ‘clusters’. Representative recent examples of the use of this technique can be found in [21] and [24]. Increasingly, clinical researchers also are using **latent class analysis** and taxometric approaches to define typologies of clinical interest, because these methods are less descriptive and more model-based than most cluster-analytic techniques. See [40] and [6], respectively, for application of these techniques to defining and measuring clinical typologies.

Evaluating Differences between Either Experimentally Created or Naturally Occurring Groups

After establishing a valid measurement model for the particular theoretical constructs of interest, clinical

researchers frequently evaluate hypothesized group differences in dependent variables (DVs) using one of many analytical models. For this class of questions, group serves as a discrete independent or quasi-independent variable (IV or QIV). In **experimental research**, group status serves as an IV, because participants are assigned randomly to groups, as in randomized controlled trials. In **quasi-experimental research**, in contrast, group status serves as a QIV, because group differences are naturally occurring, as in psychopathology research, which examines the effect of diagnostic membership on various measures. Thus, when conducting quasi-experimental research, it often is unclear whether the QIV (a) ‘causes’ any of the observed group differences; (b) results from the observed group differences; or (c) has an illusory relationship with the DV (e.g., a third variable has produced the correlation between the QIV and the DV). Campbell and Stanley [9] provide an excellent overview of the theoretical and methodological issues surrounding the distinction between quasi-experimental and experimental research and describe the limits of causality inferences imposed by the use of quasi-experimental research designs.

In contrast to the IV or QIV, the DVs can be continuous or discrete and are presumed to reflect the influence of the IV or QIV. Thus, we might be interested in (a) evaluating differences in perfectionism (the DV) for patients who are diagnosed with anorexia versus bulimia (a QIV, because patients are not assigned randomly to disorder type); (b) examining whether the frequency of rehospitalization (never, once, two or more times) over a two-year period (the DV) varies for patients whose psychosis was or was not treated with effective antipsychotic medication during the initial hospitalization (an IV, if drug assignment is random); (c) investigating whether the rate of reduction in hyperactivity (the DV) over the course of psychopharmacological treatment with stimulants is greater for children whose parents are assigned randomly to implement behavioral-modification programs in their homes (an IV); (d) assessing whether the time to a second suicide attempt (the DV) is shorter for patients who exhibit marked, rather than minimal, impulsivity (a QIV); or (e) evaluating whether a 10-day behavioral intervention versus no intervention (an IV) reduces the overall level of a single child’s disruptive behavior (the DV).

What sets apart this class of questions about the influence of an IV or QIV on a DV is the discreteness of the predictor; the DVs can be practically any statistic, whether means, proportions, frequencies, slopes, correlations, time until a particular event occurs, and so on. Thus, many statistical techniques aim to address the same meta-level research question about group differences but they make different assumptions about the nature of the DV. For example, clinical researchers commonly use ANOVA techniques to examine group differences in means (perhaps to answer question 1 above); chi-square or **log-linear** approaches to evaluate group differences in frequencies (question 2; see [52]); **growth-curve** or multilevel modeling (MLM) (see **Hierarchical Models**) techniques to assess group differences in the intercept, slope, or acceleration parameters of a regression line (question 3; see [48] for an example); survival analysis to investigate group differences in the time to event occurrence, or ‘survival time’ (question 4; see [7] and [8]); and **interrupted time-series analysis** to evaluate the effect of an intervention on the level or slope of a single participant’s behavior within a multiple-baseline design (question 5; see [42] for an excellent example of the application of this approach). Thus, these five very different analytical models all aim to evaluate very similar theoretical models about group differences. A common extension of these analytical models provides simultaneous analysis of two or more DVs (e.g., **Multivariate Analysis of Variance (MANOVA)** evaluates mean group differences in two or more DVs).

Many analyses of group differences necessitate inclusion of one or more covariates, or variables other than the IV or QIV that also are assumed to influence the DV and may correlate with the predictor. For example, a researcher might be interested in evaluating the influence of medication compliance (a QIV) on symptoms (the DV), apart from the influence of social support (the covariate). In this circumstance, researchers commonly use **Analysis of Covariance (ANCOVA)** to ‘control for’ the influence of the covariate on the DV. If participants are assigned randomly to levels of the IV, then ANCOVA can be useful for increasing the **power** of the evaluation of the effect of the IV on the DV (i.e., a true effect is more likely to be detected). If, however, participants are not assigned randomly to IV levels and the groups differ on the covariate – a common circumstance in clinical research and a likely

characteristic of the example above – then ANCOVA rarely is appropriate (i.e., this analytical model likely provides an invalid assessment of the researcher's theoretical model). This is an underappreciated matter of serious concern in psychopathology research, and readers are urged to consult [39] for an excellent overview of the relevant substantive issues.

Predicting Group Membership

Clinical researchers are interested not only in examining the effect of group differences on variables of interest (as detailed in the previous section) but also in predicting group differences. In this third class of research questions, group differences become the DV, rather than the IV or QIV. We might be interested in predicting membership in diagnostic categories (e.g., schizophrenic or not) or in predicting important discrete clinical outcomes (e.g., whether a person commits suicide, drops out of treatment, exhibits partner violence, reoffends sexually after mandated treatment, or holds down a job while receiving intensive case-management services). In both cases, the predictors might be continuous, discrete, or a mix of both. **Discriminant function analysis (DFA)** and **logistic regression** techniques commonly are used to answer these kinds of questions. Note that researchers use these methods for a purpose different than that of researchers who use the typology-definition methods discussed in the first section (e.g., cluster analysis, latent class analysis); the focus in this section is on the *prediction* of group membership (which already is known before the analysis), rather than the *discovery* of group membership (which is unknown at the beginning of the analysis).

DFA uses one or more weighted linear combinations of the predictor variables to predict group membership. For example, Hinshaw, Carte, Sami, Treuting, and Zupan [22] used DFA to evaluate how well a class of 10 neuropsychiatric variables could predict the presence or absence of attention-deficit/hyperactivity disorder (ADHD) among adolescent girls. Prior to conducting the DFA, Hinshaw and colleagues took the common first step of using MANOVA to examine whether the groups differed on a linear combination of the class of 10 variables (i.e., they first asked the group-differences question that was addressed in the previous section). Having determined that the groups differed on the class of

variables, as well as on each of the 10 variables in isolation, the authors then used DFA to predict whether each girl did or did not have ADHD. DFA estimated a score for each girl on the weighted linear combination (or discriminant function) of the predictor variables, and the girl's predicted classification was based on whether her score cleared a particular cutoff value that also was estimated in the analysis. The resulting discriminant function, or prediction equation, then could be used in other samples or studies to predict the diagnosis of girls for whom ADHD status was unknown. DFA produces a two-by-two classification table, in which the two dimensions of the table are 'true' and 'predicted' states (e.g., the presence or absence of ADHD). Clinical researchers use the information in this table to summarize the predictive power of the collection of variables, commonly using a percent-correct index, a combination of sensitivity and specificity indices, or a combination of positive and negative predictive power indices. The values of these indices frequently vary as a function of the relative frequency of the two states of interest, as well as the cutoff value used for classification purposes, however. Thus, researchers increasingly are turning to alternative indices without these limitations, such as those drawn from **signal-detection theory** [37].

Logistic regression also examines the prediction of group membership from a class of predictor variables but relaxes a number of the restrictive assumptions that are necessary for the valid use of DFA (e.g., multivariate normality, linearity of relationships between predictors and DV, and homogeneity of variances within each group). Whereas DFA estimates a score for each case on a weighted linear combination of the predictors, logistic regression estimates the probability of one of the outcomes for each case on the basis of a nonlinear (logistic) transformation of a weighted linear combination of the predictors. The predicted classification for a case is based on whether the estimated probability clears an estimated cutoff. Danielson, Youngstrom, Findling, and Calabrese [16] used logistic regression in conjunction with signal-detection theory techniques to quantify how well a behavior inventory discriminated between various diagnostic groups. At this time, logistic regression techniques are preferred over DFA methods, given their less-restrictive assumptions.

Evaluating Theoretical Models That Specify a Network of Interrelated Constructs

As researchers' theoretical models for a particular clinical phenomenon become increasingly sophisticated and complex, the corresponding analytical models also increase in complexity (e.g., evaluating a researcher's theoretical models might require the simultaneous estimation of multiple equations that specify the relationships between a network of variables). At this point, researchers often turn to either multiple-regression models (MRM) (see **Multiple Linear Regression**) or SEM to formalize their analytical models. In these models, constructs with a single measured indicator are referred to as measured (or manifest) variables; this representation of a construct makes the strong assumption that the measured variable is a perfect, error-free indicator of the underlying construct. In contrast, constructs with multiple measured indicators are referred to as latent variables; the assumption in this case is that each measured variable is an imperfect indicator of the underlying construct and the inclusion of multiple indicators helps to reduce error.

MRM is a special case of SEM in which all constructs are treated as measured variables and includes single-equation multiple-regression approaches, **path-analytic methods**, and **linear multilevel models** techniques. Suppose, for example, that you wanted to test the hypothesis that the frequency of negative life events influences the severity of depression, which in turn influences physical health status. MRM would be sufficient to evaluate this theoretical model if the measurement model for each of these three constructs included only a single variable. SEM likely would become necessary if your measurement model for even one of the three constructs included more than one measured variable (e.g., if you chose to measure physical health status with scores on self-report scale as well as by medical record review, because you thought that neither measure in isolation reliably and validly captured the theoretical construct of interest). Estimating SEMs requires the use of specialized software, such as LISREL, AMOS, M-PLUS, Mx, or EQS (see **Structural Equation Modeling: Software**).

Two types of multivariate models that are particularly central to the evaluation and advancement of theory in clinical science are those that specify either **mediation** or **moderation** relationships

between three or more variables [3]. Mediation hypotheses specify a mechanism (B) through which one variable (A) influences another (C). Thus, the example in the previous paragraph proposes that severity of depression (B) mediates the relationship between the frequency of negative life events (A) and physical health (C); in other words, the magnitude of the association between negative life events and physical health should be greatly reduced once depression enters the mix. The strong version of the mediation model states that the A-B-C path is causal and complete – in our example, that negative life events cause depression, which in turn causes a deterioration in physical health – and that the relationship between A and C is completely accounted for by the action of the mediator. Complete mediation is rare in social science research, however. Instead, the weaker version of the mediation model is typically more plausible, in which the association between A and C is reduced significantly (but not eliminated) once the mediator is introduced to the model.

In contrast, moderation hypotheses propose that the magnitude of the influence of one variable (A) on another variable (C) depends on the value of a third variable (B) (i.e., moderation hypotheses specify an interaction between A and B on C). For example, we might investigate whether socioeconomic status (SES) (B) moderates the relationship between negative life events (A) and physical health (C). Conceptually, finding a significant moderating relationship indicates that the A–C relationship holds only for certain subgroups in the population, at least when the moderator is discrete. Such subgroup findings are useful in defining the boundaries of theoretical models and guiding the search for alternative theoretical models in different segments of the population.

Although clinical researchers commonly specify mediation and moderation theoretical models, they rarely design their studies in such a way as to be able to draw strong inferences about the hypothesized theoretical models (e.g., many purported mediation models are evaluated for data collected in **cross-sectional designs** [54], which raises serious concerns from both a logical and data-analytic perspective [14]). Moreover, researchers rarely take all the steps necessary to evaluate the corresponding analytical models. Greater attention to the relevant literature on appropriate statistical evaluation of mediation and moderation

hypotheses should enhance the validity of our inferences about the corresponding theoretical models [3, 23, 28, 29].

In addition to specifying mediating or moderating relationships, clinical researchers are interested in networks of variables that are organized in a nested or hierarchical fashion. Two of the most common **hierarchical**, or multilevel, data structures are (a) nesting of individuals within social groups or organizations (e.g., youths nested within classrooms) or (b) nesting of observations within individuals (e.g., multiple symptoms scores over time nested within patients). Prior to the 1990s, options for analyzing these nested data structures were limited. Clinical researchers frequently collapsed multilevel data into a flat structure (e.g., by disaggregating classroom data to the level of the child or by using difference scores to measure change within individuals). This strategy resulted in the loss of valuable information contained within the nested data structure and, in some cases, violated assumptions of the analytic methods (e.g., if multiple youths are drawn from the same classroom, their scores will likely be correlated and violate independence assumptions). In the 1990s, however, advances in statistical theory and computer power led to the development of MLM techniques. Conceptually, MLM can be thought of as hierarchical multiple regression, in which regression equations are estimated for the smallest (or most nested) unit of analysis and then the parameters of these regression equations are used in second-order analyses. For example, a researcher might be interested in both individual-specific and peer-group influences on youth aggression. In an MLM analysis, two levels of regression equations would be specified: (a) a first-level equation would specify the relationship of individual-level variables to youth aggression (e.g., gender, attention problems, prior history of aggression in a different setting, etc.); and (b) a second-level equation would predict variation in these individual regression parameters as a function of peer-group variables (e.g., the effect of average peer socioeconomic status (SES) on the relationship between gender and aggression). In practice, these two levels are estimated simultaneously. However, given the complexity of the models that can be evaluated using MLM techniques, it is frequently useful to map out each level of the MLM model separately. For a through overview of MLM techniques and available

statistical packages, see the recent text by Raudenbush and Byrk [43], and for recent applications of MLM techniques in the clinical literature, see [41] and [18].

Researchers should be forewarned that numerous theoretical, methodological, and statistical complexities arise when specifying, estimating, and evaluating an analytical model to evaluate a hypothesized network of interrelated constructs, particularly when using SEM methods. Space constraints preclude description of these topics, but researchers who wish to test more complex theoretical models are urged to familiarize themselves with the following particularly important issues: (a) Evaluation and treatment of missing-data patterns; (b) assessment of power for both the overall model and for individual parameters of particular interest; (c) the role of capitalization on chance and the value of cross-validation when respecifying poorly fitting models; (d) the importance of considering different models for the network of variables that make predictions identical to those of the proposed theoretical model; (e) the selection and interpretation of appropriate fit indices; and (f) model-comparison and model-selection procedures (e.g., [2, 14, 25, 32, 33, 34, 51]). Finally, researchers are urged to keep in mind the basic maxim that the strength of causal inferences is affected strongly by research design, and the experimental method applied well is our best strategy for drawing such inferences. MRM and SEM analytical techniques often are referred to as causal models, but we deliberately avoid that language here. These techniques may be used to analyze data from a variety of experimental or quasi-experimental research designs, which may or may not allow you to draw strong causal inferences.

Synthesizing and Evaluating Findings Across Studies or Data Sets

The final class of research questions that we consider is research synthesis or **meta-analysis**. In meta-analyses, researchers describe and analyze empirical findings across studies or datasets. As in any other research enterprise, conducting a meta-analysis (a) begins with a research question and statement of hypotheses; (b) proceeds to data collection, coding, and transformation; and (c) concludes with analysis and interpretation of findings. Meta-analytic investigations differ from other studies in that the unit of

data collection is the *study* rather than the participant. Accordingly, 'data collection' in meta-analysis is typically an exhaustive, well-documented literature search, with predetermined criteria for study inclusion and exclusion (e.g., requiring a minimum sample size or the use of random assignment). Following initial data collection, researchers develop a coding scheme to capture the critical substantive and methodological characteristics of each study, establish the reliability of the system, and code the findings from each investigation. The empirical results of each investigation are transformed into a common metric of effect sizes (see [5] for issues about such transformations). Effect sizes then form the unit of analysis for subsequent statistical tests. These statistical analyses may range from a simple estimate of a population effect size in a set of homogenous studies to a complex multivariate model designed to explain variability in effect sizes across a large, diverse literature.

Meta-analytic inquiry has become a substantial research enterprise within clinical psychology, and results of meta-analyses have fueled some of the most active debates in the field. For example, in the 1980s and 1990s, Weisz and colleagues conducted several reviews of the youth therapy treatment literature, estimated population effect sizes for the efficacy of treatment versus control conditions, and sought to explain variability in these effect sizes in this large and diverse treatment literature (e.g., [56]). Studies included in the meta-analyses were coded for theoretically meaningful variables such as treatment type, target problem, and youth characteristics. In addition, studies were classified comprehensively in terms of their methodological characteristics – from the level of the study (e.g., sample size, type of control group) down to the level of each individual outcome measure, within each treatment group, within each study (e.g., whether a measure was an unnecessarily reactive index of the target problem). This comprehensive coding system allowed the investigators to test the effects of the theoretical variables of primary interest as well as to examine the influence of methodological quality on their findings. Results of these meta-analyses indicated that (a) structured, behavioral treatments outperformed unstructured, nonbehavioral therapies across the child therapy literature; and (b) psychotherapy in everyday community clinic settings was more likely to entail use of nonbehavioral treatments and to have lower effect sizes than those seen in research studies of

behavioral therapies (e.g., [55]). The debate provoked by these meta-analytic findings continues, and the results have spurred research on the moderators of therapy effects and the dissemination of evidence-based therapy protocols to community settings.

As our example demonstrates, meta-analysis can be a powerful technique to describe and explain variability in findings across an entire field of inquiry. However, meta-analysis is subject to the same limitations as other analytic techniques. For example, the effects of a meta-analysis can be skewed by biased sampling (e.g., an inadequate literature review), use of a poor measurement model (e.g., an unreliable scheme for coding study characteristics), low power (e.g., an insufficiently large literature to support testing cross-study hypotheses), and data-quality problems (e.g., a substantial portion of the original studies omit data necessary to evaluate meta-analytic hypotheses, such as a description of the ethnicity of the study sample). Furthermore, most published meta-analyses do not explicitly model the nested nature of their data (e.g., effect sizes on multiple symptom measures are nested within treatment groups, which are nested within studies). Readers are referred to the excellent handbook by Cooper and Hedges [15] for a discussion of these and other key issues involved in conducting a meta-analysis and interpreting meta-analytic data.

Overarching Principles That Underlie the Use of Statistics in Clinical Psychology

Having provided an overview of the major research questions and associated analytical techniques in clinical psychology, we turn to a brief explication of four principles and associated corollaries that characterize the responsible use of statistics in clinical psychology. The intellectual history of these principles draws heavily from the work and insight of such luminaries as **Jacob Cohen**, Alan Kazdin, Robert McCallum, and Paul Meehl. Throughout this section, we refer readers to more lengthy articles and texts that expound on these principles.

Principle 1: The specification and evaluation of theoretical models is critical to the rapid advancement of clinical research.

Corollary 1: Take specification of theoretical, measurement, and analytical models seriously. As theoretical models specify unobserved constructs and

their interrelationships (see earlier section on defining and measuring constructs), clinical researchers must draw inferences about the validity of their theoretical models from the fit of their analytical models. Thus, the strength of researchers' theoretical inferences depends critically on the consistency of the measurement and analytical models with the theoretical models [38]. Tightening the fit between these three models may preclude the use of 'off-the-shelf' measures or analyses, when existing methods do not adequately capture the constructs or their hypothesized interrelationships. For example, although more than 25 years of research document the outstanding psychometric properties of the BDI, the BDI emphasizes the cognitive and affective aspects of the construct of depression more than the vegetative and behavioral aspects. This measurement model may be more than sufficient for many investigations, but it would not work well for others (e.g., a study targeting sleep disturbance). Neither measurement nor analytical models are 'assumption-free', so we must attend to the psychometrics of measures (e.g., their reliability and validity), as well as to the assumptions of analytical models. Additionally, we must be careful to maintain the distinctions among the three models. For example, clinical researchers tend to collapse the theoretical and measurement models as work progresses in a particular area (e.g., we reify the construct of depression as the score on the BDI). McFall and Townsend [36] provide an eloquent statement of this and related issues.

Corollary 2: Pursue theory-driven, deductive approaches to addressing research questions whenever possible, and know the limitations of relying on more inductive strategies. Ad hoc storytelling about the results of innumerable exploratory data analyses is a rampant research strategy in clinical psychology. Exploratory research and data analysis often facilitate the generation of novel theoretical perspectives, but it is critical to replicate the findings and examine the validity of a new theoretical model further before taking it too seriously.

Principle 2: The heart of the clinical research enterprise lies in model (re-)specification, evaluation, and comparison.

Corollary 1: Identify the best model from a set of plausible alternatives, rather than evaluating the adequacy of a single model. Clinical researchers often

evaluate a hypothesized model only by comparing it to models of little intrinsic interest, such as a null model that assumes that there is no relationship between the variables or a saturated model that accounts perfectly for the observed data. Serious concerns still may arise in regard to a model that fits significantly better than the null model and nonsignificantly worse than the saturated model, however, (see [51] for an excellent overview of the issues that this model-fitting strategy raises). For example, a number of equivalent models may exist that make predictions identical to those of the model of interest [34]. Alternatively, nonequivalent alternative models may account as well or better for the observed data. Thus, methodologists now routinely recommend that researchers specify and contrast competing theoretical models (both equivalent and nonequivalent) because this forces the researcher to specify and evaluate a variety of theoretically based explanations for the anticipated findings [34, 51].

Corollary 2: Model modifications may increase the validity of researchers' theoretical inferences, but they also may capitalize on sampling variability. When the fit of a model is less than ideal, clinical researchers often make post hoc modifications to the model that improve its fit to the observed data set. For example, clinical researchers who use SEM techniques often delete predictor variables, modify the links between variables, or alter the pattern of relationships between error terms. Other analytic techniques also frequently suffer from similar overfitting problems (e.g., stepwise regression (see **Regression Models**), DFA). These data-driven modifications improve the fit of the model significantly and frequently can be cast as theoretically motivated. However, these changes may do little more than capitalize on systematic but idiosyncratic aspects of the sample data, in which case the new model may not generalize well to the population as a whole [33, 51]. Thus, it is critical to cross-validate respecified models by evaluating their adequacy with data from a new sample; alternatively, researchers might develop a model on a randomly selected subset of the sample and then cross-validate the resulting model on the remaining participants. Moreover, to be more certain that the theoretical assumptions about the need for the modifications are on target, it is

important to evaluate the novel theoretical implications of the modified model with additional data sets.

Principle 3: Mastery of research design and the mechanics of statistical techniques is critical to the validity of researchers' statistical inferences.

Corollary 1: Know your data. Screening data is a critical first step in the evaluation of any analytical model. Inspect and address patterns of missing data (e.g., pair-wise deletion, list-wise deletion, estimation of missing data). Evaluate the assumptions of statistical techniques (e.g., normality of distributions of errors, absence of outliers, linearity, homogeneity of variances) and resolve any problems (e.g., make appropriate data transformations, select alternative statistical approaches). Tabachnick and Fidell [50] provide an outstanding overview of the screening process in the fourth chapter of their multivariate text.

Corollary 2: Know the power of your tests. Jacob Cohen [10] demonstrated more than four decades ago that the **power** to detect hypothesized effects was dangerously low in clinical research, and more recent evaluations have come to shockingly similar conclusions [47, 49]. Every clinical researcher should understand how sample size, effect size, and α affect power; how low power increases the likelihood of erroneously rejecting our theoretical models; and how exceedingly high power may lead us to retain uninteresting theoretical models. Cohen's [12] power primer is an excellent starting place for the faint of heart.

Corollary 3: Statistics can never take you beyond your methods. First, remember GIGO (garbage in–garbage out): Running statistical analyses on garbage measures invariably produces garbage results. Know and care deeply about the psychometric properties of your measures (e.g., various forms of reliability, validity, and **generalizability**; see [26] for a comprehensive overview). Second, note that statistical techniques rarely can eliminate confounds in your research design (e.g., it is extremely difficult to draw compelling causal inferences from quasi-experimental research designs). If your research questions demand quasi-experimental methods, familiarize yourself with designs that minimize threats to

the internal and external validity of your conclusions [9, 26].

Principle 4: Know the limitations of Null-Hypothesis Statistical Testing (NHST).

Corollary 1: The alternative or research hypotheses tested within the NHST framework are very imprecise and almost always true at a population level. With enough power, almost any two means will differ significantly, and almost any two variables will show a statistically significant correlation. This weak approach to the specification and evaluation of theoretical models makes it very difficult to reject or falsify a theoretical model, or to distinguish between two theoretical explanations for the same phenomena. Thus, clinical researchers should strive to develop and evaluate more precise and risky predictions about clinical phenomena than those traditionally examined with the NHST framework [11, 13, 31, 38]. When the theoretical models in a particular research area are not advanced enough to allow more precise predictions, researchers are encouraged to supplement NHST results by presenting **confidence intervals** around sample statistics [31, 35].

Corollary 2: P values do not tell you the likelihood that either the null or alternative hypothesis is true. *P* values specify the likelihood of observing your findings if the null hypothesis is true – *not* the likelihood that the null hypothesis is true, given your findings. Similarly, $(1.0 - p)$ is not equivalent to the likelihood that the alternative hypothesis is true, and larger values of $(1.0 - p)$ do not mean that the alternative hypothesis is more likely to be true [11, 13]. Thus, as Abelson [1] says, 'Statistical techniques are aids to (hopefully wise) judgment, not two-valued logical declarations of truth or falsity' (p. 9–10).

Corollary 3: Evaluate practical significance as well as statistical significance. The number of 'tabular asterisks' in your output (i.e., the level of significance of your findings) is influenced strongly by your sample size and indicates more about reliability than about the practical importance of your findings [11, 13, 38]. Thus, clinical researchers should report information on the practical significance, or magnitude, of their effects, typically by presenting effect-size indices and the confidence intervals around them [13,

45, 46]. Researchers also should evaluate the adequacy of an effect's magnitude by considering the domain of application (e.g., a small but reliable effect size on mortality indices is nothing to scoff at!).

Conclusions

Rapid advancement in the understanding of complex clinical phenomena places heavy demands on clinical researchers for thoughtful articulation of theoretical models, methodological expertise, and statistical rigor. Thus, the next generation of clinical psychologists likely will be recognizable in part by their quantitative sophistication. In this article, we have provided an overview of the use of statistics in clinical psychology that we hope will be particularly helpful for students and early career researchers engaged in advanced statistical and methodological training. To facilitate use for teaching and training purposes, we organized the descriptive portion of the article around core research questions addressed in clinical psychology, rather than adopting alternate organizational schemes (e.g., grouping statistical techniques on the basis of mathematical similarity). In the second portion of the article, we synthesized the collective wisdom of statisticians and methodologists who have been critical in shaping our own use of statistics in clinical psychological research. Readers are urged to consult the source papers of this section for thoughtful commentary relevant to all of the issues raised in this article.

Clinical Trials and Intervention Studies

The Intervention Study

In a controlled observational **cohort study**, two groups of subjects are selected from two populations that (hopefully) differ in only one characteristic at the start. The groups of subjects are studied for a specific period and contrasted at the end of the study period. For instance, smokers and nonsmokers are studied for a period of 10 years, and at the end the proportions of smokers and nonsmokers that died in that period are compared. On the other hand, in an intervention study, the subjects are selected from one population with a particular characteristic present; then, immediately after baseline, the total study group is split up into a group that receives the intervention and a group that does not receive that intervention (control group). The comparison of the outcomes of the two groups at the end of the study period is an evaluation of the intervention. For instance, smokers can be divided into those who will be subject to a smoking-cessation program and those who will not be motivated to stop smoking.

Interventions have the intention to improve the condition of an individual or a group of individuals. Some examples of intervention studies in public health research are studies that evaluate the impact of a program: (a) to promote a healthier lifestyle (avoiding smoking, reducing alcohol drinking, increasing physical activity, etc.), (b) to prevent HIV-transmission, (c) to start brushing teeth early in babies, and so on. Ample intervention studies can also be found in other disciplines; two examples illustrate this. First, Palmer, Brown, and Barrera [4] report on an intervention study that tests a short-term group program for abusive husbands against a control program. The two groups are compared with respect to the recidivism rates of the men regarding abuse of their female partners. Second, Moens et al. [1] evaluated in a controlled intervention study the effect of teaching of how to lift and transfer patients to nursing students in a nursing school. After two years of follow-up, the incidence risk of one or more episodes of back pain was compared between the two groups of nursing students.

Controlled clinical trials constitute a separate but important class of intervention studies. There, the aim is to compare the effectiveness and safety of two (or more) medical treatments or surgical operations or combinations thereof. Clearly, now the target population constitutes patients with a specific disease or symptom. More aspects of clinical trials will be highlighted in section 'Typical Aspects of Clinical Trials'.

Intervention studies are often applied on an individual level but they can also be applied on a group level. For instance, promoting better brushing habits for children could be done on an individual basis, for example, by means of a personal advice to the parents of the child, or on a group basis, for example, by introducing special courses on good brushing habits in school. Intervention studies operating on a group level need dedicated statistical methods. We will start with the intervention studies on individual level but come back to intervention studies on group level in section 'Intervention Studies on Group Level'.

Basic Aspects of an Intervention Study

The first step in any intervention study is to specify the target population, which is the population to which the findings should be extrapolated. This requires a specific definition of the subjects in the study prior to selection. In a clinical trial, this is achieved by specifying inclusion and exclusion criteria. In general, the inclusion criteria specify the type of patients who need the treatment under examination and the exclusion criteria exclude patients for which there will be most likely safety concerns or for which the treatment effect might not be clear, for example, because they are already on another, competing, treatment.

To obtain a clear idea about the effect of the intervention, the two groups (intervention and control) should be comparable at the start. More specifically, at baseline, the two groups should be selected from the same population – only in that case a difference between the two groups at the end of the study is a sign of an effect of the intervention. Comparability or balance at baseline is achieved by randomly allocating subjects to the two groups; this is known as randomization. Simple **randomization** corresponds to tossing a coin and when (say) heads, the subject will receive the intervention and in the other

case (s)he will be in the control group. But other randomization schemes exist, like block- and stratified randomization (see **Block Random Assignment; Stratification**). It is important to realize that randomization can only guarantee balance for large studies and that random imbalance can often occur in small studies.

For several types of intervention studies, balance at baseline is a sufficient condition for an interpretable result at the end. However, in a clinical trial we need to be more careful. Indeed, while most interventions aim to achieve a change in attitude (a psychological effect), medical treatments need to show their effectiveness apart from their psychological impact, which is also called the *placebo effect*. The **placebo effect** is the pure psychological effect that a medical treatment can have on a patient. This effect can be measured by administering placebo (inactive medication with the same taste, texture, etc. as the active medication) to patients who are blinded for the fact that they haven't received active treatment. Placebo-controlled trials, that is, trials with a placebo group as control, are quite common. When only the patient is unaware of the administered treatment, the study is called *single-blinded*. Sometimes, also the treating physician needs to be blinded, if possible, in order to avoid bias in scoring the effect and safety of the medication. When patients as well as physician(s) are blinded, we call it a double-blinded clinical trial. Such a trial allows distinguishing the biological effect of a drug from its psychological effect.

The advantage of randomization (plus blinding in a clinical trial) is that the analysis of the results can often be done with simple statistical techniques such as an unpaired *t* Test for continuous measurements or a chi-squared test for categorical variables. This is in contrast to the analysis of controlled observational cohort studies where **regression models** are needed to take care of the imbalance at baseline since subjects are often self-selected in the two groups.

To evaluate the effect of the intervention, a specific outcome needs to be chosen. In the context of clinical trials, this outcome is called the *endpoint*. It is advisable to choose one endpoint, the primary endpoint, to avoid multiple-testing issues. If this is not possible, then a correction for multiple testing such as a Bonferroni adjustment (see **Multiple Comparison Procedures**) is needed. The choice of the primary endpoint has a large impact on the design of the study, as will be exemplified in the section 'Typical Aspects

of Clinical Trials'. Further, it is important that the intervention study is able to detect the anticipated effect of the intervention with a high probability. To this end, the necessary sample size needs to be determined such that the **power** is high enough (in clinical trials, the minimal value nowadays equals 0.80).

Although not a statistical issue, it is clear that any intervention study should be ethically sound. For instance, an intervention study is being set up in South Africa where on the one hand adolescents are given guidelines of how to avoid HIV-transmission and on the other hand, for ethical reasons, adolescents are given general guidelines to live a healthier life (like no smoking, etc.). In clinical trials, ethical considerations are even more of an issue. Therefore, patients are supposed to sign an informed consent document.

Typical Aspects of Clinical Trials

The majority of clinical trials are drug trials. It is important to realize that it takes many years of clinical research and often billions of dollars to develop and register a new drug. In this context, clinical trials are essential, partly because regulatory bodies like the Food and Drug Administration (FDA) in the United States and the European Medicine Agency (EMA) in Europe have imposed stringent criteria on the pharmaceutical industry before a new drug can be registered. Further, the development of a new drug involves different steps such that drug trials are typically subdivided into phases. Four phases are often distinguished. Phase I trials are small, often involve volunteers, and are designed to learn about the drug, like establishing a safe dose of the drug, establishing the schedule of administration, and so on. Phase II trials build on the results of phase I trials and study the characteristics of the medication with the purpose to examine if the treatment should be used in large-scale randomized studies. Phase II designs usually involve patients, are sometimes double blind and randomized, but most often not placebo-controlled. When a drug shows a reasonable effect, it is time to compare it to a placebo or standard treatment; this is done in a phase III trial. This phase is the most rigorous and extensive part of the investigation of the drug. Most often, phase III studies are double-blind, controlled, randomized, and involve many centers (often hospitals); it is the typical controlled clinical trial as

introduced above. The size of a phase III trial will depend on the anticipated effect of the drug. Such studies are the basis for registration of the medication. After approval of the drug, large-scale studies are needed to monitor for (rare) adverse effects; they belong to the phase IV development stage.

The typical clinical trial design varies with the phase of the drug development. For instance, in phase I studies, an **Analysis of variance** design comparing the different doses is often encountered. In phase II studies, **crossover designs**, whereby patients are randomly assigned to treatment sequences, are common. In phase III studies, the most common design is the simple parallel-group design where two groups of patients are studied over time after drug administration. Occasionally, three or more groups are compared; when two (or more) types of treatments are combined, a factorial design is popular allowing the estimation of the effects of each type of treatment.

Many phase III trials need a lot of patients and take a long time to give a definite answer about the efficacy of the new drug. For economic as well as ethical reasons, one might be interested in having an idea of the effect of the new drug before the planned number of patients is recruited and/or is studied over time. For this reason, one might want to have interim looks at the data, called *interim analyses*. A clinical trial with planned interim analyses has a so-called group-sequential design indicating that specific statistical (correction for multiple testing) and practical (interim meetings and reports) actions are planned. Usually, this is taken care of by an independent committee, called the *Data and Safety Monitoring Board* (DSMB). The DSMB consists of clinicians and statisticians overlooking the efficacy but especially the safety of the new drug.

Most of the clinical trials are superiority trials with the aim to show a better performance of the new drug compared to the control drug. When the control drug is not placebo but a standard active drug, and it is conceived to be difficult to improve upon the efficacy of that standard drug, one might consider showing that the new drug has comparable efficacy. When the new drug is believed to have comparable efficacy and has other advantages, for example, a much cheaper cost, a noninferiority trial is an option. For a noninferiority trial, the aim is to show that the new medication is not (much) worse than the standard treatment (*see Equivalence Trials*).

Currently, noninferiority trials are becoming quite frequent due to the difficulty to improve upon existing therapies.

The choice of the primary endpoint can have a large impact on the design of the study. For instance, changing from a binary outcome evaluating short-term survival (say at 30 days) to survival time as endpoint not only changes the statistical test from a chi-square test to, say, a logrank test but can also have a major practical impact on the trial. For instance, with long-term survival as endpoint, a group-sequential design might become a necessity.

Despite the fact that most clinical trials are carefully planned, many problems can occur during the conduct of the study. Some examples are as follows: (a) patients who do not satisfy the inclusion and/or exclusion criteria are included in the trial; (b) a patient is randomized to treatment A but has been treated with B; (c) some patients drop out from the study; (d) some patients are not compliant, that is, do not take their medication as instructed, and so on. Because of these problems, one might be tempted to restrict the comparison of the treatments to the ideal patients, that is, those who adhered perfectly to the clinical trial instructions as stipulated in the protocol. This population is classically called the *per-protocol population* and the analysis is called the *per-protocol analysis*. A per-protocol analysis envisages determining the biological effect of the new drug. However, by restricting the analysis to a selected patient population, it does not show the practical value of the new drug. Therefore, regulatory bodies push the **intention-to-treat** (ITT) analysis forward. In the ITT population, none of the patients is excluded and patients are analyzed according to the randomization scheme. Although medical investigators have often difficulties in accepting the ITT analysis, it is the pivotal analysis for FDA and EMEA.

Although the statistical techniques employed in clinical trials are often quite simple, recent statistical research tackled specific and difficult clinical trial issues, like dropouts, compliance, noninferiority studies, and so on. Probably the most important problem is the occurrence of dropout in a clinical trial. For instance, when patients drop out before a response can be obtained, they cannot be included in the analysis, even not in an ITT analysis. When patients are examined on a regular basis, a series of measurements is obtained. In that case, the measurements obtained before the patient dropped out can be used

to establish the unknown measurement at the end of the study. FDA has been recommending for a long time the Last-Observation-Carried-Forward (LOCF) method. Recent research shows that this method gives a biased estimate of the treatment effect and underestimates the variability of the estimated result [6]. More sophisticated methods are reviewed in [7] (*see Missing Data*).

Intervention Studies on Group Level

Many intervention studies act on the group level; they are called *group-randomized studies*. For instance, Murray et al. [2] describe an intervention study to evaluate four interventions to reduce the tobacco use among adolescents. Forty-eight schools were randomized to the four interventions. After two years of follow-up, the proportion of children using 'smokeless tobacco' was compared. The proportions found in two of the four treatment groups were $58/1341 = 0.043$ and $91/1479 = 0.062$. A simple chi-square test gives a P value of 0.03. However, this test assumes independence of the subjects. When adolescents are motivated in a school context, there will be a high interaction among adolescents of the same class/school, that is, the outcome of one adolescent will depend on the outcome of another adolescent. Hence, the chi-square test is not appropriate. An adjusted chi-square test taking the correlation among the adolescents into account (see [2]) gives a P value of 0.18.

In general, the appropriate statistical techniques for group-randomized studies need to take the correlation among subjects in the same group into account (*see Intraclass Correlation*). This implies the use of techniques like **Generalized Estimating Equations** (GEE) and random effects models; see, for

example, [7] and **Linear Multilevel Models; Generalized Linear Models (GLM)**.

Further Reading

An excellent source for clinical trial methodology can be found in [5]. Intervention studies operating on group level gained in importance the last decade; for an overview of these designs, we refer to [3].

Cluster Analysis: Overview

Research in various fields gives rise to large data sets of high-dimension where the structure of the underlying processes is not well-enough understood to construct informative models to estimate parameters. *Cluster analysis* is an exploratory method designed to elicit information from such data sets. It is exploratory in that the analyst is more interested in generating hypotheses than in testing them. Researchers generally use cluster analysis as a heuristic tool to gain insight into a set of data. Cluster analysis seeks to reduce the dimensionality of data by grouping objects into a small number of groups, or clusters, whose members are more similar to each other than they are to objects in other clusters. Because it is heuristic, there is wide variation in cluster analysis techniques and algorithms (*see Hierarchical Clustering; k-means Analysis*). Cluster analysis is widely used because it provides useful information in different areas, ranging from identifying genes that have similar function [3] to identifying market segments that have similar consumers.

Many researchers are unwilling to make the assumption of ‘crisp’ group membership, that is, that a person is in only one group. This has led to the extension of cluster analysis to admit the concept of partial group membership and to ‘fuzzy’ clusters ([12], *see Fuzzy Cluster Analysis*).

Cluster analysis works with results of multiple measurements made on a sample of individuals. In this case, initial data may be represented in the form of matrix

$$\mathbf{X} = \begin{pmatrix} x_1^1 & \cdots & x_p^1 \\ \vdots & \ddots & \vdots \\ x_1^n & \cdots & x_p^n \end{pmatrix}, \quad (1)$$

where x_j^i is a result of j th measurement on i th individual. In the terminology of cluster analysis, rows of the matrix $\mathbf{X}$ are referred as *cases*, and columns as *variables*.

Given the data array, (1) (*see Multivariate Analysis: Overview*), the objective is to group objects into clusters of similar objects based on attributes that objects possess. The ‘objects’ are the cases (or rows) of (1), each case having values for each of p variables, $\mathbf{x}^i = (x_1^i, \dots, x_p^i)$. For example, if rows

in (1) represent genes, and attributes are gene expression values (phenotypes) measured under experimental conditions, one might be interested to see which genes exhibit similar phenotypes and functions.

One might find it appropriate to consider variables (columns) as objects of interest, each variable having an attribute value on each of n cases $\mathbf{x}_j = (x_j^1, \dots, x_j^n)$. One important application for which clustering variables is appropriate is in questionnaire design to identify sets of questions that measure the same phenomenon. In other applications, it may make sense to simultaneously cluster cases and variables (*see Two-mode Clustering*).

When cases or variables may be considered as realizations of random vectors, and the probability density function of this random vector is multimodal (with relatively small number of modes), natural clustering will create clusters around the modes. Multimodal probability density functions often arise when the observed distribution is a **finite mixture** [4]. For categorical data, equivalents of finite mixture models are latent class models [18, 17, 11]. Again, natural clustering in this case will produce clusters corresponding to latent classes. In this sense, cluster analysis relates to latent class models in the case of categorical data, and to finite mixture models in the case of continuous data (*see Model Based Cluster Analysis*).

This article identifies common cluster analysis variants and discusses their uses. We will illustrate cluster analysis variants using two data sets, (1) individual disability measures from the National Long Term Care Survey (NLTCs) and (2) multiple software metrics on a number of modules developed as part of a worldwide customer service system for a lodging business.

Distance Measures

A notion of ‘similarity’ is the cornerstone of cluster analysis. Quantitatively, similarity is expressed as a *distance* between cases (variables): the less the distance, the more similar are the cases (variables). Cluster algorithms are based on two distances (a) $d(\mathbf{x}_j, \mathbf{x}_k)$, the distance, measured in a suitable metric, between the two vectors, $\mathbf{x}_j$ and $\mathbf{x}_k$ (in examples of distance below, we define distance between variables; distance between cases is defined in exactly the same way), and (b) the distance between two clusters, $D(c_1, c_2)$.

2 Cluster Analysis: Overview

There are many ways to define $d(\mathbf{x}_j, \mathbf{x}_k)$ (see **Proximity Measures**). New ones can be readily constructed. The suitability of any given measure is largely in the hands of the researcher, and is determined by the data, objectives of the analysis, and assumptions. Although, in many cases, distance is a metric on the space of cases or variables (i.e., it satisfies (a) $d(\mathbf{x}_j, \mathbf{x}_k) \geq 0$; $d(\mathbf{x}_j, \mathbf{x}_k) = 0$ if, and only if, $\mathbf{x}_j = \mathbf{x}_k$; (b) $d(\mathbf{x}_j, \mathbf{x}_k) = d(\mathbf{x}_k, \mathbf{x}_j)$; (c) $d(\mathbf{x}_j, \mathbf{x}_l) \leq d(\mathbf{x}_k, \mathbf{x}_j) + d(\mathbf{x}_k, \mathbf{x}_l)$), the last condition, the *triangle inequality*, is not necessary for the purpose of cluster analysis, and, often, is not used. In the examples below, (2) and (4) are metrics, while (3) is not; (5) is a metric if, and only if, $p = r$.

For measured variables, the standard *Euclidean distance* is often used where the distance between two objects, x_j and x_k , is,

$$d(\mathbf{x}_j, \mathbf{x}_k) = \left(\sum_{i=1}^n (x_k^i - x_j^i)^2 \right)^{1/2}. \quad (2)$$

It is sometimes appropriate to emphasize large distances; in this case, the square of the Euclidean distance could be appropriate

$$d(\mathbf{x}_j, \mathbf{x}_k) = \sum_{i=1}^n (x_k^i - x_j^i)^2. \quad (3)$$

If one suspects the data contains outliers, and desires to reduce their effect, then the distance could be defined as the so-called *Manhattan distance* (named to reflect its similarity with the path a taxi travels between two points in an urban area)

$$d(\mathbf{x}_j, \mathbf{x}_k) = \sum_{i=1}^n |x_k^i - x_j^i|. \quad (4)$$

The distances defined above are special cases of the general formula

$$d(\mathbf{x}_j, \mathbf{x}_k) = \left(\sum_{i=1}^n |x_j^i - x_k^i|^p \right)^{1/p}, \quad (5)$$

where p and r are parameters used to control the behavior of the distance measure in the presence of outliers or small values.

For categorical attributes (i.e., for attributes that take values from an unordered finite state), the

Hamming distance is used:

$$d(\mathbf{x}_j, \mathbf{x}_k) = \sum_{i=1}^n (1 - \delta(x_k^i, x_j^i)),$$

$$\text{where } \delta(x_k^i, x_j^i) = \begin{cases} 1, & \text{if } x_k^i = x_j^i \\ 0, & \text{if } x_k^i \neq x_j^i \end{cases}. \quad (6)$$

The Hamming distance is the number of places in which $\mathbf{x}_j$ and $\mathbf{x}_k$ differ.

It is important that attributes be measured in the same units: otherwise, the unit of the distance measure is not defined. If attributes are measured principally in different units (say, length and weight), one possibility to overcome this obstacle is to replace dimensional values by dimensionless ratios to mean values, that is, replace x_j^i by $x_j^i / \sum_{k=1}^n x_j^k$.

If a statistical package does not support a desired distance measure, it will usually accept an externally computed distance matrix in lieu of raw data.

Just as there is a plethora of inter-object distance measures, there are also many ways to define intercluster distances. **Hierarchical clustering** algorithms are defined by the measure of intercluster distance used.

A *single-linkage* distance between two clusters is a distance between nearest members of these clusters,

$$D_s(c_1, c_2) = \min_{\mathbf{x}_j \in c_1, \mathbf{x}_k \in c_2} d(\mathbf{x}_j, \mathbf{x}_k). \quad (7)$$

A *complete linkage* distance between two clusters is a distance between most distant members of these clusters,

$$D_c(c_1, c_2) = \max_{\mathbf{x}_j \in c_1, \mathbf{x}_k \in c_2} d(\mathbf{x}_j, \mathbf{x}_k). \quad (8)$$

An *average linkage* or UPGA (unweighted pair group average) distance is just an average distance between pairs of objects taken one from each of two clusters,

$$D_a(c_1, c_2) = \frac{1}{M} \sum_{\mathbf{x}_j \in c_1, \mathbf{x}_k \in c_2} d(\mathbf{x}_j, \mathbf{x}_k), \quad (9)$$

where M is a total number of all possible pairs (number of summands in the sum). In the case when objects may be considered as a vector in Euclidean space (i.e., when all measurements x_j^i are real numbers and the Euclidean distance (2) is used), the average linkage distance between two

clusters is the Euclidean distance between their centers of gravity.

All the above distances between clusters possess one property, crucial for efficiency of hierarchical clustering algorithms: if a cluster c_2 is a union of clusters c'_2 and c''_2 , then the distance from any cluster c_1 to the cluster c_2 is readily expressed via distances $D(c_1, c'_2)$ and $D(c_1, c''_2)$. Namely,

$$\begin{aligned} D_s(c_1, c_2) &= \min(D_s(c_1, c'_2), D_s(c_1, c''_2)) \\ D_c(c_1, c_2) &= \max(D_c(c_1, c'_2), D_c(c_1, c''_2)) \\ D_a(c_1, c_2) &= \frac{1}{M' + M''} (M' \times D_a(c_1, c'_2) \\ &\quad + M'' \times D_a(c_1, c''_2)), \end{aligned} \quad (10)$$

Again, if a statistical package does not support a desired distance measure, it will usually accept an external procedure to compute $D(c_1, c_2)$ from $D(c_1, c'_2)$ and $D(c_1, c''_2)$.

The choice of distance measure has a significant impact on the result of a clustering procedure. This choice is usually dictated by the subject domain, and all reasonable possibilities have to be carefully investigated. One important case, which leads to a unique (and, in some sense, ideal) clusterization, is the *ultrametricity* of the distance (see **Ultrametric Inequality**). The distance $d(\mathbf{x}, \mathbf{y})$ is called *ultrametric*, if it satisfies the requirement $d(\mathbf{x}, \mathbf{z}) \leq \max(d(\mathbf{x}, \mathbf{y}), d(\mathbf{y}, \mathbf{z}))$. This requirement is stronger than the triangle inequality $d(\mathbf{x}, \mathbf{z}) \leq d(\mathbf{x}, \mathbf{y}) + d(\mathbf{y}, \mathbf{z})$, and implies a number of good properties. Namely, the clusters constructed by the hierarchical clustering algorithm (described below) have the properties: (a) the distance between two members of two clusters does not depend on the choice of these members, that is, if $\mathbf{x}$ and $\mathbf{x}'$ are vectors corresponding to members of a cluster c_1 , and $\mathbf{y}$ and $\mathbf{y}'$ correspond to members of a cluster c_2 , then $d(\mathbf{x}, \mathbf{y}) = d(\mathbf{x}', \mathbf{y}')$; moreover, all the distances between clusters defined above coincide, and are equal to the distance between any pair of their members, $D_s(c_1, c_2) = D_c(c_1, c_2) = D_a(c_1, c_2) = d(\mathbf{x}, \mathbf{y})$; (b) the distance between any two members of one cluster is smaller than the distance between any member of this cluster and any member of another cluster, $d(\mathbf{x}, \mathbf{x}') \leq d(\mathbf{x}, \mathbf{y})$.

Hierarchical Clustering Algorithm

A main objective of cluster analysis is to define a cluster so that it is, in some sense, as 'far' from other clusters as possible. A hierarchical clustering algorithm starts by assigning each object to its own cluster. Then, at each step, the pair of closest clusters is combined into one cluster. This idea may be implemented very efficiently by first writing distances between objects as a matrix,

$$\begin{pmatrix} d(x_1, x_1) & d(x_1, x_2) & \cdots & d(x_1, x_p) \\ d(x_2, x_1) & d(x_2, x_2) & \cdots & d(x_2, x_p) \\ \vdots & \vdots & \ddots & \vdots \\ d(x_p, x_1) & d(x_p, x_2) & \cdots & d(x_p, x_p) \end{pmatrix}. \quad (11)$$

This is a symmetric matrix with the diagonal elements equal to 0; thus, it can be stored as an upper triangle matrix. A step consists of the following:

1. Find the smallest element of this matrix; let it be in row j and column j' . As the matrix is upper triangular, we have always $j < j'$. The clusters j and j' are to be combined on this step. Combining may be considered as removal of the cluster j' and replacing cluster j by the union of clusters j and j' .
2. Remove row j' and column j' from the matrix and recalculate values in row j and column j'' using (10).

Here, one can see the importance of the property of distance between clusters given by (10): the distances in the matrix at the beginning of a step are sufficient to calculate new distances; one does not need to know distances between all members of the clusters.

The results of a hierarchical cluster analysis are presented as a *dendrogram*. One axis of a dendrogram is the intercluster distance; the identity of objects is displayed on the other.

Horizontal lines in Figure 1 connect a cluster with its parent cluster; the lengths of the lines indicate distances between the clusters. Where does one slice the dendrogram? It can be at a prespecified measure of dissimilarity, or at a point that yields a certain number of clusters. Wallace [24] suggests stopping at a point on the dendrogram where 'limbs are long and there are not many branches' (see **Number of Clusters**).

Figure 1 Dendrogram

Depending on the choice of the distance measure between clusters, the resulting clusterization possesses different properties. The single-linkage clustering tends to produce an elongated chain of clusters. Because of ‘chaining’, single-linkage clustering has fallen out of favor [16], though it has attractive theoretical properties. In one dimension, this distance metric seems the obvious choice. It is also related to the **minimum spanning tree (MST)** [7]. The MST is the graph of minimum length connecting all data points. Single-linkage clusters can be arrived at by successively deleting links in the MST [10]. Single-linkage is consistent in one dimension [10]. Complete linkage and average linkage algorithms work best when the data has a strong clustering tendency.

***k*-means Clustering**

In hierarchical clustering, the number of clusters is not known *a priori*. In *k*-means clustering, suitable only for quantitative data, the number of clusters, *k*, is assumed known (see ***k*-means Analysis**).

Every cluster c_k is characterized by its *center*, which is the point $\mathbf{v}_k$ that minimizes the sum

$$\sum_{\mathbf{x}_j \in c_k} d(\mathbf{x}_j, \mathbf{v}_k). \quad (12)$$

Again, it is possible to use different notions of distance; however, *k*-means clustering is significantly more sensitive to the choice of distance, as the

minimization of (12) may be a very difficult problem. Usually, the squared Euclidean distance is used; in this case, the center of a cluster is just its center of gravity, which is easy to calculate.

Objects are allocated to clusters so that the sum of distances from objects to the centers of clusters to which they belong, taken over all clusters, is minimal. Mathematically, this means minimization of

$$\sum_{k=1}^K \sum_{\mathbf{x}_j \in c_k} d(\mathbf{x}_j, \mathbf{v}_k), \quad (13)$$

which depends on continuous vector parameters $\mathbf{v}_k$ and discrete parameters representing membership in clusters. This is a nonlinear constrained optimization problem, and has no obvious analytical solution. Therefore, heuristic methods are adopted; the one most widely used is described below.

First, the centers of clusters $\mathbf{v}_k$ are randomly chosen (or, equivalently, objects are randomly assigned to clusters and the centers of clusters are calculated). Second, each object $\mathbf{x}_j$ is assigned to a cluster c_k whose center is the nearest to the object. Third, centers of clusters are recalculated (based on the new membership) and the second step repeated. The algorithm terminates when the next iteration does not change membership.

Unfortunately, the result to which the above algorithm converges depends on the first random choice of clusters. To obtain a better result, it is recommended to perform several runs of the algorithm and then select the best result.

The advantage of the k -means clustering algorithm is its low computational complexity: on every step, only $n \times k$ (where n is the number of objects) distances have to be calculated, while hierarchical clustering requires computation of (approximately) $n^2/2$ distances. Thus, k -means clustering works significantly faster than hierarchical clustering when k is much smaller than n , which is the case in many practical situations. However, it is hard to determine the right number of clusters in advance. Therefore, some researchers recommend performing a hierarchical clustering algorithm on a subsample to estimate k , and then performing a k -means algorithm on the complete data set.

Wong [25] proposed a hybrid clustering method that does the reverse, that is, a k -means algorithm is used to compute an empirical distribution on n observations from which k clusters are defined. Then, a single-linkage hierarchical algorithm is used to cluster the clusters found by k -means algorithm. The second clustering starts with a $k \times k$ distance matrix *between clusters*. The intercluster distance between neighboring clusters is defined by the distance between closest neighboring objects. The distance between non-neighboring clusters is defined to be infinite. The method is ‘set-consistent’ for one dimension [25]. Consistency for higher dimensions remains a conjecture. Using the k -means algorithm for a first step makes for a computationally efficient algorithm suitable for large data sets. Wong [26] developed a single-linkage procedure that does not use the k -means first step and is set-consistent in high dimensions, but it is suitable only for small samples.

Disabilities Example

The first example uses the NLTCs, a nationally representative longitudinal survey of persons aged 65 and older, and conducted by the Center for Demographic Studies at Duke University. The survey is a probability sample from US Medicare Eligibility Files. Survey waves are conducted every five years, and, for each wave, a nationally representative sample of persons who have become 65 since the prior wave is added to the total survey sample. Disability is assessed by the presence of ADLs or IADLs. An Activity of Daily Living (ADL) is an essential

Table 1 Disability measures

1	Help Eating
2	Help getting in and out of bed
3	Help getting around inside
4	Help dressing
5	Help bathing
6	Help using toilet
7	Is bedfast
8	No inside activity
9	Is wheelchairfast
10	Help with heavy work
11	Needs help with light work
12	Help with laundry
13	Help with cooking
14	Help with grocery shopping
15	Help getting about outside
16	Help traveling
17	Help managing money
18	Help taking medicine
19	Help telephoning
20	Climbing one flight of stairs
21	Bend for socks
22	Hold 10 lb. package
23	Reach over head

25	Washing hair
26	Grasping small objects
27	Reading newspaper

activity of daily living such as eating or toileting for which one requires help. An Instrumental Activity of Daily Living (IADL) is an activity such as grocery shopping or traveling for which one requires help. At each wave, the survey screens individuals with a short survey instrument, and those that are determined to be disabled (one or more ADLs or IADLs lasting for than 90 days), residing either in the community or in an institution, are given a more detailed set of questions. The NLTCs data to be used here is for one survey wave and consists of 5089 observations with 19 questions about disabilities having a binary response, and eight questions about the degree of difficulty in performing certain activities having four responses: no difficulty, some difficulty, much difficulty, or cannot perform the activity at all. The questions (variables) are listed in Table 1. We will use this data to illustrate three algorithms (single-linkage, complete linkage, and UPGA) applied to the first 50 cases in the data set. We restricted the example because more than 50 cases resulted in dendograms too difficult to read. We will also use this data to

Figure 2 Fifty cases From NLTCs Data set clustered by three linkage algorithms

do a cluster analysis of variables. Since all questions have categorical responses, we use the percent difference measure of dissimilarity as the distance function (6).

Figure 2 presents the results from the dendrograms from the three hierarchical algorithms run on the first 50 NLTCs cases. Clusters for the single-linkage algorithm tend to form a chain-like structure. The two other algorithms give more compact results. The dendrograms have the 50 cases identified on the vertical axis. The horizontal axis scale is the

distance measure. To read a dendrogram, select a distance on the horizontal axis and draw a vertical line at that point. Every line in the dendrogram that is cut defines a cluster *at that distance*. The length of the horizontal lines represents distances between clusters. While the three dendrograms appear to have the same distance metric, distances are calculated differently.

Since the distance measures are defined differently, we cannot cut each dendrogram at a fixed distance, say 0.5, and expect to get comparable results.

Instead, we start at the top of the tree where every object is a member of a single cluster and cut immediate level two. In the UPGA dendrogram, that cut will be at approximately 0.42; in the single-linkage dendrogram, that cut will be at 0.45, and in the complete-linkage dendrogram, at about 0.8. These cuts define 4, 7, and 7 clusters, respectively. The UPGA cluster sizes were {2, 32, 8, 8}; the single-linkage cluster sizes were {1, 1, 1, 1, 2, 44}, and the complete-linkage cluster sizes were {3, 1, 5, 6, 33, 6, 7}. In practice, one would examine the cases that make up each cluster.

These algorithms can be used to cluster variables by reversing the roles of variables and cases in distance calculations. Variables in the data set were split into two sets according to outcome sets. The complete-linkage clustering was used.

The results of the first 19 variables, which had binary response sets, are displayed in Figure 3. At a distance of 0.3, the variables divide into two clusters. Moving about inside or outside, bathing, grocery shopping, traveling, and heavy work make up one cluster. The remaining 13 variables make up the second cluster. The second cluster could be seen as being two subclusters: (1) in/out-bed, dressing, toileting, light work, cooking, and laundry; and (2) activities that indicate a greater degree of disability (help eating, being bedfast, wheelchair-fast, etc.).

The remaining eight variables that each have four responses were also analyzed. The results are

in Figure 4. At a distance of 0.5, the variables fit into three sets. Climbing a single flight of stairs (one-flight-stairs) comprises its own cluster; socks (bending for) and holding a 10 pound package comprise another; and combing hair, washing hair, grasping an object and reading a newspaper constitute a third.

Software Metrics Example

The second data set consists of 26 software metrics measured on the source code of 180 individual software modules that were part of an international customer service system for a large lodging business. The modules were all designed and developed according to Michael Jackson methods [13, 14]. The measurements included Halstead measures [8] of vocabulary, volume, length, McCabe complexity [5], as well as other measures such as comments, number of processes. The original analysis determined if there were modules that should be rewritten. This second set will be analyzed by *k*-means clustering. The original analysis was done using **Principal Component Analysis** [13, 14], and that analysis is presented here for comparison.

In the original Principal Component Analysis, since the variables were on such different scales, and to keep one variable from dominating the analysis, variables were scaled to have equal variances. The resulting covariance matrix (26 variables) was

Figure 3 Tree diagram for 19 disability measures complete-linkage dissimilarity measure = percent disagreement

singular, so analyses used the generalized inverse. The two largest eigenvalues accounted for a little over 76% of the variance. The data was transformed by the eigenvectors associated with the two largest eigenvalues and plotted in Figure 5. The circles indicate the five clusters identified by the eye.

The analysis identified clusters, but does not tell us which programs are bad. Without other information, the analysis is silent. One could argue that we know we have a good process and, therefore, any deviant results must be bad. In this case, three of the programs in the smaller clusters had repeatedly missed deadlines and, therefore, could be considered bad. Other clusters were similar. Two clusters differed from the main body of programs on one eigenvector and not on the other. The other two small clusters differed from the main body on both eigenvectors.

We analyzed the same data by k -means clustering with $k = 4$. The four clusters contained 5, 9, 29, and 145 objects. Cluster 1 consisted of the five objects in the three most remote clusters in Figure 5. Cluster 3 was made up of the programs in Figure 5, whose names are far enough away from the main body to have visible names. Clusters 2 and 4 were the largest and break up the main body of Figure 4.

Conclusions

The concept of cluster analysis first appeared in the literature in the 1950s and was popularized by [22, 21, 1, 9], and others. It has recently enjoyed increased interest as a data-mining tool for understanding large volumes of data such as gene expression experiments and transaction data such as online book sales or occupancy records in the lodging industry.

Cluster analysis methods are often simple to use in practice. Procedures are available in commonly used statistical packages (e.g., SAS, STATA, STATISTICA, and SPSS) as well as in programs devoted exclusively to cluster analysis (e.g., CLUSTAN). Algorithms tend to be computationally intensive. The analyses presented here were done using STATISTICA 6.1 software (see **Software for Statistical Analyses**).

Cluster analyses provide insights into a wide variety of applications without many statistical assumptions. Further examples of cluster analysis applications are (a) identifying of market segments

from transaction data; (b) estimating of readiness of accession countries to join the European Monetary Union [2]; (c) understanding benign prostate hyper trophy (BHP) [6]; (d) studying antisocial behavior [15]; (e) to study southern senatorial voting [19]; (f) studying multiple planetary flow regimes [20]; and (g) reconstructing of fossil organisms [23]. The insights they provide, because of a lack of a formal statistical theory of inference, require validating in other venues where formal hypothesis tests can be used.

Clustered Data

There are many studies in the behavioral sciences that give rise to data that are clustered. Clustered data commonly arise when intact groups are assigned to interventions or when naturally occurring groups in the population are sampled. An example of the former is cluster-randomized trials. In a cluster-randomized trial, groups of individuals, rather than the individuals themselves, are randomized to different interventions and data on the outcomes of interest are obtained on all individuals within a group. Alternatively, clustered data can arise from random sampling of naturally occurring groups in the population. Families, households, neighborhoods, and schools are all instances of naturally occurring clusters that might be the primary sampling units in a study. Clustered data also arise when data on the outcome of interest are simultaneously obtained either from multiple raters or from different measurement instruments. Finally, longitudinal and repeated measures studies give rise to clustered data (*see* **Longitudinal Data Analysis; Repeated Measures Analysis of Variance**). In these studies, the cluster is composed of the repeated measurements obtained from a single individual at different occasions or under different conditions.

Although we have distinguished between clustering that occurs naturally and clustering due to study design, the consequence of clustering is the same: units that are grouped in a cluster are likely to respond more similarly. Intuitively, we might reasonably expect that measurements on units within a cluster are more alike than the measurements on units in different clusters. For example, two children

selected at random from the same family are expected to respond more similarly than two children randomly selected from different families. In general, the degree of clustering can be represented by positive correlation among the measurements on units within the same cluster (*see* **Intraclass Correlation**). This within-cluster correlation can be thought of as a measure of the homogeneity of responses within a cluster relative to the variability of such responses between clusters. The intraclass correlation invalidates the crucial assumption of independence that is the cornerstone of so many standard statistical techniques. As a result, the straightforward application of standard regression models (e.g., **multiple linear regression** for a continuous response or **logistic regression** for a binary response) to clustered data is no longer valid unless some allowance for the clustering is made.

From a statistical standpoint, the main feature of clustered data that needs to be accounted for in any analysis is the fact that units from the same cluster are likely to respond more similarly. As a consequence, clustered data may not contain quite as much information as investigators might otherwise like to believe it does. In general, neglecting to account for clusters in the data will lead to incorrect estimates of precision. For example, when estimating averages or comparing averages for groups of clusters, failure to account for clustering will result in estimated standard errors that are too small, **confidence intervals** that are too narrow, and *P* values that are too small. In summary, failure to make some adjustment to the nominal standard errors to correct for clusters in the data can result in quite misleading scientific inferences.

Cochran, William Gemmell

Born: July 15, 1909, in Rutherglen, Scotland.

Died: March 29, 1980, in Orleans, Massachusetts.

William Cochran was born into a family of modest means in a suburb of Glasgow. In 1927, he was awarded a bursary that allowed him to take his first degree at Glasgow University; he obtained an M.A. in mathematics and physics in 1931, and a scholarship to St John's College, Cambridge. At Cambridge, he took the only course in mathematical statistics then available and produced a paper on the distribution of quadratic forms, now known as *Cochran's theorem* [1]. But Cochran did not finish his Ph.D. studies in Cambridge because in 1934, **Frank Yates**, who had just become head at Rothamsted Experimental Station on Fisher's departure to the Galton Chair at University College, offered him a job, which he accepted.

During his six years at Rothamsted, Cochran worked on experimental design and sample survey techniques, publishing 29 papers. He worked closely with Yates and also spent time with **Fisher**, who was a frequent visitor to Rothamsted. A visit to the Iowa Statistical Laboratory in 1938 led to the offer of a

statistics post from **George Snedecor**, and in 1939, Cochran emigrated to the United States.

In the United States, Cochran continued to apply sound experimental techniques in agriculture and biology, and after World War II, he moved to the newly formed Institute of Statistics in North Carolina to work with **Gertrude Cox**. Their collaboration led, in 1950, to the publication of what quickly became the standard textbook on experimental design [2]. In 1957, Cochran was appointed head of the Department of Statistics at Harvard, where he remained until his retirement in 1976.

Cochran was made president of the Biometric Society from 1954 to 1955 and vice president of the American Association for the Advancement of Science in 1966. In 1974, he was elected to the US National Academy of Science. Cochran was an outstanding teacher and among his 40 or so doctoral students are many who have become internationally famous leaders in a variety of areas of statistics.

Cochran's C Test

Cochran's [1] C test is used to examine model assumptions made when applying **analysis of variance (ANOVA)**. The simple model equation in a one-factorial ANOVA is $Y_{ij} = \mu + \alpha_j + \varepsilon_{ij}$, for $i = 1, \dots, n$ and $j = 1, \dots, p$. In this equation, Y_{ij} is the observation for case i in treatment category j , μ is the grand mean, α_j is the j th treatment, and ε_{ij} is the residual of Y_{ij} . According to the model equation, there are three core assumptions for ANOVA:

1. The model contains all sources of the variation that affect Y_{ij} ;
2. The experiment involves all of the treatment effects of interest; and
3. The residuals are independent of each other, are normally distributed within each treatment population, and have a mean of 0 and constant variance, σ^2 .

The last part of the third assumption is known as the assumption of *homogeneity of residual variances*, or *homoscedasticity*. Written in the form of a null hypothesis, this assumption is

$$H_0: \sigma_1^2 = \sigma_2^2 = \dots = \sigma_p^2. \quad (1)$$

The alternative hypothesis is $\sigma_j^2 \neq \sigma_{j'}^2$, for some j and j' and $j \neq j'$. In a fashion similar to tests of distributional assumptions, the ANOVA model requires that this null hypotheses be retained. If this hypothesis can be retained, standard ANOVA can be performed. Otherwise, that is, in the case of *heteroscedasticity*, nonparametric approaches such as the **Kruskal–Wallis test** may be more suitable.

There exists a number of tests of homogeneity of residual variances. If the design is orthogonal (sample sizes are the same under each treatment), the tests from Hartley, Leslie and Brown, and Levene, or Cochran's test are suitable. If the design is nonorthogonal (samples sizes differ across treatment conditions), Bartlett's test is suitable (for a more detailed treatment see [3, 4]).

Because of its simple mathematical definition, Cochran's C test, together with Hartley's test, is a so-called *easy-to-use* test. Hartley [2] proposes calculating an F-ratio by dividing the maximum of the empirical variances by their minimum (over the

various treatments). In most cases, Hartley's and Cochran's tests lead to the same results. Cochran's test, however, tends to be more powerful (*see Power*), because it uses more of the information in the data. A second reason why Cochran's test may be preferable is that it performs better when one treatment variance is substantially larger than all other treatment variances. Cochran's test statistic is

$$C = \frac{\sigma_{\max}^2}{\sum_{j=1}^p \sigma_j^2}, \quad (2)$$

where $\sigma_{\max}^2$ is the largest of the p sample variances, and $\sum_{j=1}^p \sigma_j^2$ is the sum of all treatment variances. Cochran [1] calculated the theoretical distribution of this ratio. Thus, it is possible to test the null hypothesis of homoscedasticity. Degrees of freedom are equal to p and $n - 1$, and the critical values are tabulated [1].

Consider the following hypothetical data example [5]. Five populations have been studied with the following sample variances: $s_1^2 = 26$; $s_2^2 = 51$; $s_3^2 = 40$; $s_4^2 = 24$; $s_5^2 = 28$. It is obvious that the second variance is substantially larger than the other variances. Therefore, this variance is placed in the numerator of the formula for C . Suppose, each of these variances is based on $df = 9$, and $\alpha = 0.05$. The application of the above formula yields $C = 0.302$. The critical value is 0.4241. The calculated value is smaller. Therefore, we retain the null hypothesis of variance homogeneity. This core assumption of an ANOVA application is met.

Table 1 summarizes Sachs' [5] recommendations for tests of homoscedasticity under various conditions.

Table 1 Testing homoscedasticity under various conditions

Population	Recommended test
Skewed	Cochran
Normal $N(\mu, \sigma)$	For $p < 10$: Hartley, Cochran; for $p \geq 10$: Bartlett
Platykurtic, that is, flatter than $N(\mu, \sigma)$	Levene
Leptokurtic, that is, taller than $N(\mu, \sigma)$	For $p < 10$: Cochran; for $p \geq 10$: Levene

Coefficient of Variation

Although the coefficient of variation (CV) is defined for both distributions and for samples, it is in the latter context, as a descriptive measure for data, that it is generally encountered.

The CV of a sample of data is defined as the sample standard deviation (SD) divided by the sample mean (m), that is,

$$CV = \frac{SD}{m}. \quad (1)$$

The value is sometimes expressed as a percentage. Two important characteristics of the CV are that it is independent of both the units of measurement and the magnitude of the data.

Suppose that we measure the times taken by right-handed subjects to complete a tracking task using a joystick held in either the right hand or the left hand. The mean and SD of times for the right-hand joystick (RH) group are 5 sec and 1 sec, and those for the left-hand (LH) group are greater at 12 sec and 1.5 sec. Then, $CV_{RH} = 1/5 = 0.20$, whereas $CV_{LH} = 1.5/12 = 0.125$.

Here, we see that the *relative* variability is greater for the RH group even though the SD is only two-thirds of that for the LH group.

Equally well, if we had counted also the number of errors (e.g., deviations of more than some fixed

amount from the required route), the CV would allow us to compare the relative variability of errors to that of times because it does not depend on the units of measurement.

The notion of the CV is generally attributed to **Karl Pearson** [2]. In an early article from 1896, which attempts to provide a theoretical framework for **Galton's** rather informal ideas on correlation and regression, Pearson used the CV for assessing the relative variability of data on variables ranging from stature of family members to skull dimensions of ancient and modern races. Pearson pointed specifically to the fact that differences in relative variability indicate 'inequality of mutual correlations' (or, similarly, of mutual regressions).

A more recent application of the CV, especially relevant to behavioral researchers working in experimental fields, is as a means of assessing within subject variability [1].

Cohen, Jacob

Jacob Cohen's contributions to statistical analysis in the behavioral sciences reflected his lifelong perspective as a data-analyst, insisting that the role of statistics was to help scientists answer the questions motivating any given study, and that there was no substitute for human judgment in this process [3]. Cohen's best-known contributions began when he called attention to the poor statistical **power** of much psychological research [1] and developed readily applied methods of estimating such power in planned research [2, 4]. Such estimates were necessarily based on the probability of rejecting the null hypothesis with an acceptably low level of statistical significance (*alpha level*). Ironically, among his last contributions to methodological developments in the field was a rejection of a statistical criterion as the central basis for interpreting study findings.

Cohen entered City College of New York (CCNY) at the age of 15, following graduation from Townsend Harris High School in New York. After two years of dismal performance (except in ping pong), he worked in war-related occupations and then enlisted in the Army Intelligence Service in time to participate in the final year of World War II in France. Upon returning to the US, he completed his undergraduate education at CCNY (1947) and his doctoral degree in clinical psychology at New York University (1950), writing a dissertation based on **factor analyses** of the Wechsler IQ test in samples of patients and comparison groups. In the beginning, during his studies, Cohen carried out research in the Veteran's Administration and continued thereafter as staff psychologist and director of research while also teaching on a part-time basis. During those years, he developed Cohen's *kappa* statistic (see **Rater Agreement – Kappa**) [1], a measure of chance-corrected agreement later further elaborated to take partial agreement into account. In 1959, he was appointed to full-time faculty status in the psychology department at New York University, where he remained as head of quantitative psychology until his retirement in 1993. Throughout these years and until his death, Cohen consulted on research design and data analysis at nearly every behavioral research and university site in the city, especially at New York

State Psychiatric Institute. He was president of the *Society for Multivariate Experimental Psychology* in 1969 and honored with a lifetime achievement award by Division 7 of the *American Psychological Association* in 1997.

Cohen's first widely influential work followed an analysis of the *statistical power* of studies published in the 1960 *Journal of Abnormal and Social Psychology* [2]. His development of rough norms for small, medium, and large **effect sizes** and easily used methods for estimating statistical power for a planned study made his book *Statistical Power Analysis for the Behavioral Sciences* [4] the classic in its field, with widely used subsequent editions and eventually computer programs. His second major contribution to the field was the adoption of *multiple regression analysis as a general data analytic system* [3, 7]. In these books and articles, Cohen employed the accessible language and conversational style that also made his work, particularly his 1990 'Things I have learned (so far)' and 1994 'The earth is round ($p < .05$)', so widely appreciated [5, 6]. His name also appeared in the top rung of citation indices in the behavioral sciences over an extended period.

Cohort Sequential Design

Two broad approaches are very common for the investigation of human development in time: individuals of different ages are studied at only one point in time (i.e., cross-sectional) (*see* **Cross-sectional Design**), or the same subjects are assessed at more than one – and preferable many – points in time (i.e., longitudinal) (*see* **Longitudinal Data Analysis**). The limitations of cross-sectional designs are well known [12, 16]. Differences in different cohorts of children at 3 years of age, 5 years, and 7 years can be due to age effects of the different individuals in each cohort as well as due to the experiences of the different individuals in each cohort. Cross-sectional studies fail to provide insight into the underlying life course mechanisms of development, whether they are societal, institutional, or personal because they confound age and cohort effects.

Longitudinal studies, in contrast, focus on the change within individuals over time and, hence, address directly the limitations of the cross-sectional approach. Longitudinal designs do not confound cohort and age, because the same individuals are assessed at each age. Although problems of true longitudinal designs are frequently reported in the methodological literature, they are often overlooked [8, 10, 22]. The most important substantial disadvantage of longitudinal designs is that age trends may reflect historical (time of measurement) effects during the study rather than true developmental change. In methodological terms, age and period effects are confounded (*see* **Confounding Variable; Quasi-experimental Designs**). This makes it hard to know the degree to which results specific to one cohort can be generalized to other cohorts. Another important practical disadvantage is that the same individuals must be followed repeatedly and tested at many different times. The amount of time it takes to complete a longitudinal study makes it very expensive and increases the chance on attrition (loss of subjects from refusal, tracing difficulties, etc.). In addition, there is a real risk that findings, theories, methods, instrumentation, or policy concerns may be out-of-date by the time data collection and analysis end. Finally, participants can be affected by repeated measurements.

Therefore, researchers have long argued that alternative approaches that maintain the advantages of the

longitudinal design but minimize its disadvantages were needed. The accelerated longitudinal design was first proposed by Bell [3, 4]. He advocated the method of ‘convergence’ as a means for meeting research needs not satisfied by either longitudinal or cross-sectional methods. This method consists of limited repeated measurements of independent age cohorts, resulting in temporally overlapping measurements of the various age groups. This technique, also termed as *cross-sequential design* [20], *the cohort-sequential design* [16], or *mixed longitudinal design* [5], provides a means by which adjacent segments consisting of limited longitudinal data on a specific age cohort can be linked together with small, overlapping segments from other temporally related age cohorts to determine the existence of a single developmental curve. The researcher, therefore, approximates a long-term longitudinal study by conducting several short-term longitudinal studies of different age cohorts simultaneously. In addition, this technique allows the researcher to determine whether those trends observed in the repeated observations are corroborated within short time periods for each age cohort. By assessing individuals of different ages on multiple occasions, cohort-sequential designs permit researchers to consider cohort and period effects, in addition to age changes [7, 13, 21].

Recently, Prinzie, Onghena, and Hellinckx [17] used an accelerated design to investigate developmental trajectories of externalizing problem behavior in children from 4 to 9 years of age. Table 1 represents their research design. Four cohorts (4, 5, 6, and 7 years of age at the initial assessment) have been assessed annually for three years. These age cohorts were ‘approximately staggered’ [14], meaning that the average age of the first cohort at the second measurement period was about the same as the average age of the second cohort at the initial measurement, and so forth. One row represents one longitudinal design and one column represents one cross-sectional design. Table 1 demonstrates that, for one row, age and period are completely confounded, and that, for one column, age and cohort are completely confounded. The more cross sections are added, the more the entanglement of age and cohort is rectified. As illustrated by Table 1, three annual measurements (1999–2001) of four cohorts span an age range of 6 years (from 4 to 9 years of age). In this study, the same developmental model was assumed in each age cohort, allowing for tests of hypotheses

2 Cohort Sequential Design

Table 1 Accelerated longitudinal design with four cohorts and three annual assessments with an age range from 4 to 9 years of age

Cohort	Period 1999 (Years)	2000 (Years)	2001 (Years)
Cohort 1	4	5	6
Cohort 2	5	6	7
Cohort 3	6	7	8
Cohort 4	7	8	9

concerning convergence across separate groups and the feasibility of specifying a common growth trajectory over the 6 years represented by the latent variable cohort-sequential design (see below).

Advantages and Disadvantages

A noticeable advantage of the cohort-sequential over the single-cohort longitudinal design is the possibility to study age effects independent of period and cohorts effects, but only if different cohorts are followed up between the same ages in different periods. Another advantage is the shorter follow-up period. This reduces the problems of cumulative testing effects and attrition, and produces quicker results. Finally, tracking several cohorts, rather than one, allows the researcher to determine whether those trends observed in the repeated observations are corroborated within short time periods for each age cohort. Two basic principles should be considered when designing cohort-sequential studies: efficiency of data collection and sufficiency of overlap. According to Anderson [1, p. 147], a proper balance between these two principles can be achieved by ensuring that (a) at least three data points overlap between adjacent groups, and (b) the youngest age group is followed until they reach the age of the oldest group at the first measurement.

The main disadvantage of the cohort-sequential design in comparison with the single-cohort longitudinal design is that within-individual developmental sequences are tracked over shorter periods. As a result, some researchers have questioned the efficacy of the cohort-sequential approach in adequately recovering information concerning the full longitudinal curve from different cohort segments when the criterion of convergence is not met. The cohort-sequential design is not the most appropriate design

for the investigation of long-term causal effects that occur without intermediate effects or sequences (e.g., between child abuse and adult violence). In addition, questions remain concerning the ability of the cohort-sequential approach to assess the impact of important events and intervening variables on the course of development [19].

Statistical Analysis

Several data-analytical strategies are developed to analyze data from a cohort-sequential design. The most well known are matching cross-cohorts based on statistical tests of significance, the use of **structural equation modeling** and **Linear multilevel models**. Bell [4] linked cohorts by matching characteristics of the subjects using a method he described as '*ad hoc*'. Traditional **analysis of variance** and regression methods (see **Multiple Linear Regression**) have been employed for cohort linkage and are criticized by Nesselroade and Baltes [16]. More recently, two statistical approaches have been proposed to depict change or growth adequately: the *hierarchical linear model* [6, 18] and the latent curve analysis (see **Structural Equation Modeling: Latent Growth Curve Analysis**) [11, 14, 15]. Both approaches have in common that growth profiles are represented by the parameters of initial status and the rate of change (see **Growth Curve Modeling**). The hierarchical linear model is easier for model specification, is more efficient computationally in yielding results and provide a flexible approach that allows for missing data, unequal spacing of time points, and the inclusion of time-varying and between-subject covariates measured either continuously or discretely. The latent curve analysis has the advantage of providing model evaluation, that is, an overall test of goodness of fit, and is more flexible in modeling and hypothesis testing. The separate cohorts' developmental paths are said to converge to a single developmental path if a model that assumes unequal paths produces results that are not statistically distinguishable from results produced by a simpler model that specifies a single path. Chou, Bentler, and Pentz [9] and Wendorf [23] compared both techniques and concluded that both approaches yielded very compatible results. In fact, both approaches might have more in common than once thought [2].

Cohort Studies

Background

Cohort studies constitute a central epidemiologic approach to the study of relationships between personal characteristics or exposures and the occurrence of health-related events, and hence to the identification of disease prevention hypotheses and strategies.

Consider a conceptually infinite population of individuals moving forward in time. A cohort study involves sampling a subset of such individuals and observing the occurrence of events of interest, generically referred to as *disease events*, over some follow-up period. Such a study may be conducted to estimate the rates of occurrence of the diseases to be ascertained, but most often, estimation of relationships between such rates and individual characteristics or exposures is the more fundamental study goal. If cohort-study identification precedes the follow-up period, the study is termed *prospective*, while a retrospective or historical cohort study involves cohort identification after a conceptual follow-up period (see **Prospective and Retrospective Studies**). This presentation assumes a prospective design.

Other research strategies for studying exposure-disease associations, and for identifying disease prevention strategies, include **case-control studies** and randomized controlled disease prevention trials. Compared to case-control studies, cohort studies have the advantages that a wide range of health events can be studied in relation to exposures or characteristics of interest and that prospectively ascertained exposure data are often of better quality than the retrospectively obtained data that characterize case-control studies. On the other hand, a cohort study of a particular association would typically require much greater cost and longer duration than would a corresponding case-control study, particularly if the study disease is rare. Compared to randomized controlled trials, cohort studies have the advantage of allowing study of a broad range of exposures or characteristics in relation to health outcomes of interest, and typically of much simplified study logistics and reduced cost. Randomized intervention trials can also examine a broad range of exposures and disease associations in an observational manner, but the randomized assessments are necessarily restricted to

examining the health consequences of a small number of treatments or interventions. On the other hand, disease prevention trials have the major advantage that the intervention comparisons are not confounded by prerandomization disease risk factors, whether or not these are even recognized. The choice among research strategies may depend on the distribution of the exposures in the study population and on the ability to reliably measure such exposures, on the knowledge and measurement of confounding factors, on the reliability of outcome ascertainment, and on study costs in relation to the public health potential of study results.

There are many examples of associations that have been identified or confirmed using cohort study techniques, including that between cigarette smoking and lung cancer; between blood pressure, blood cholesterol, cigarette smoking, and coronary heart disease; between current use of the original combined oral contraceptives and the risk of various vascular diseases; and between atomic bomb radiation exposure and the risk of leukemia or of various solid tumors, to name a few. In recent years, there have also been many examples of the use of cohort study designs to examine the association between exposures that are difficult to measure, or that may have limited within-cohort exposure variability, and the occurrence of disease. Such examples may involve, for example, physical activity, dietary, environmental, or occupational exposures, and behavioral characteristics. In these settings, cohort studies sometimes yield weak or equivocal results, and multiple cohort studies of the same general association may yield contradictory results. It is important to be able to anticipate the reliability (see **External Validity; Internal Validity**) **power** of cohort studies, to be aware of strategies for enhancing study power and reliability, and to carefully consider optimal research strategies for assessing specific exposure-disease hypotheses.

Basic Cohort Study Elements

Exposure Histories and Disease Rates

A general regression (see **Regression Models**) notation can be used to represent the exposures (and characteristics) to be ascertained in a cohort study. Let $z_1(u)^T = \{z_{11}(u), z_{12}(u), \dots\}$ denote a set of numerically coded variables that describe an individual's characteristics at 'time' u , where, to be specific,

u can be defined as time from selection into the cohort, and ' T ' denotes vector transpose. Let $Z_1(t) = \{z_1(u), u < t\}$ denote the history of such characteristics at times less than t . Note that the 'baseline' exposure data $Z_1(0)$ may include information that pertains to time periods prior to selection into the cohort. Denote by $\lambda\{t; Z_1(t)\}$ the population **incidence** (hazard) rate at time t for a disease of interest, as a function of an individual's preceding 'covariate' history. A typical cohort study goal is the elucidation of the relationship between aspects of $Z_1(t)$ and the corresponding disease rate $\lambda\{t; Z_1(t)\}$. As mentioned above, a single cohort study may be used to examine many such covariate-disease associations.

The interpretation of the relationship between $\lambda\{t; Z_1(t)\}$ and $Z_1(t)$ may well depend on other factors. Let $Z_2(t)$ denote the history up to time t of a set of additional characteristics. If the variates $Z_1(t)$ and $Z_2(t)$ are related among population members at risk for disease at time t and if the disease rate $\lambda\{t; Z_1(t), Z_2(t)\}$ depends on $Z_2(t)$, then an observed relationship between $\lambda\{t; Z_1(t)\}$ and $Z_1(t)$ may be attributable, in whole or in part, to $Z_2(t)$. Hence, toward an interpretation of causality, one can focus instead on the relationship between $Z_1(t)$ and the disease rate function $\lambda\{t; Z_1(t), Z_2(t)\}$, thereby controlling for the 'confounding' influences of Z_2 . In principle, a cohort study needs to control for all pertinent confounding factors in order to interpret a relationship between Z_1 and disease risk as causal. It follows that a good deal must be known about the disease process and disease risk factors before an argument of causality can be made reliably. This feature places a special emphasis on the replication of results in various populations, with the idea that unrecognized or unmeasured confounding factors may differ among populations. As noted above, the principle advantage of a randomized disease prevention trial, as compared to a purely observational study, is that the randomization indicator variable $Z_1 = Z_1(0)$, where here $t = 0$ denotes the time of randomization, is unrelated to the histories $Z_2(0)$ of all confounding factors, whether or not such are recognized or measured.

The choice as to which factors to include in $Z_2(t)$, for values of t in the cohort follow-up period, can be far from being straightforward. For example, factors on a causal pathway between $Z_1(t)$ and disease risk may give rise to 'over adjustment' if included in $Z_2(t)$, since one of the mechanisms

whereby the history $Z_1(t)$ alters disease risk has been conditioned upon. On the other hand, omission of such factors may leave a confounded association, since the relationship between Z_2 and disease risk may not be wholly attributable to the effects of Z_1 on Z_2 .

Cohort Selection and Follow-up

Upon identifying the study diseases of interest and the 'covariate' histories $Z(t) = \{Z_1(t), Z_2(t)\}$ to be ascertained and studied in relation to disease risk, one can turn to the estimation of $\lambda\{t; Z(t)\}$ based on a cohort of individuals selected from the study population. The basic cohort selection and follow-up requirement for valid estimation of $\lambda\{t; Z(t)\}$ is that at any $\{t, Z(t)\}$ a sample that is representative of the population in terms of disease rate be available and under active follow-up for disease occurrence. Hence, conceptually, cohort selection and censoring rates (e.g., loss to follow-up rates) could depend arbitrarily on $\{t, Z(t)\}$, but selection and follow-up procedures cannot be affected in any manner by knowledge about, or perception of, disease risk at specified $\{t, Z(t)\}$.

Covariate History Ascertainment

Valid estimation of $\lambda\{t; Z(t)\}$ requires ascertainment of the individual study subject histories, Z , during cohort follow-up. Characteristics or exposures prior to cohort study enrollment are often of considerable interest, but typically need to be ascertained retrospectively, perhaps using specialized questionnaires, using analysis of biological specimens collected at cohort study entry, or by extracting information from existing records (e.g., employer records or occupational exposures). Postenrollment exposure data may also need to be collected periodically over the cohort study follow-up period to construct the histories of interest. In general, the utility of cohort study analyses depends directly on the extent of variability in the 'covariate' histories Z , and in the ability to document that such histories have been ascertained in a valid and reliable fashion. It often happens that aspects of the covariate data of interest are ascertained with some measurement error, in which case substudies that allow the measured quantities to be related to the underlying variables of interest (e.g., validation

or reliability substudies) may constitute a key aspect of cohort study conduct.

Disease Event Ascertainment

A cohort study needs to include a regular updating of the occurrence times for the disease events of interest. For example, this may involve asking study subjects to report a given set of diagnoses or health-related events (e.g., hospitalization) that initiate a process for collecting hospital and laboratory records to determine whether or not a disease event has occurred. Diagnoses that require considerable judgment may be further adjudicated by a panel of diagnostic experts. While the completeness of outcome ascertainment is a key feature of cohort study quality, the most critical outcome-related cohort study feature concerns whether or not there is differential outcome ascertainment, either in the recognition or the timely ascertainment of disease events of interest, across the exposures or characteristics under study. Differential ascertainment can often be avoided by arranging for outcome ascertainment procedures and personnel to be independent to exposure histories, through document masking and other means.

Data Analysis

Typically, a test of association between a certain characteristic or exposure and disease risk can be formulated in the context of a descriptive statistical model. With occurrence-time data, the Cox regression model [4], which specifies

$$\lambda\{t; Z(t)\} = \lambda_0(t) \exp\{X(t)^T \beta\}, \quad (1)$$

is very flexible and useful for this purpose. In this model, λ_0 is a 'baseline' disease rate model that need not be specified, $X(t)^T = \{X_1(t), \dots, X_p(t)\}$ is a modeled regression vector formed from $Z(t)$, and $\beta^T = (\beta_1, \dots, \beta_p)$ is a corresponding hazard ratio (**relative risk**) parameter to be estimated. Testing and estimation on β is readily carried out using a so-called partial likelihood function [5, 7]. For example, if X_1 defines an exposure variable (or characteristic) of interest, a test of $\beta_1 = 0$ provides a test of the hypothesis of no association between such exposure and disease risk over the cohort follow-up period, which controls for the potential confounding factors

coded by $X_2, \dots, X_p$. Virtually all statistical software packages include tests and **confidence intervals** on β under this model, as well as estimators of the cumulative baseline hazard rate.

The data-analytic methods for accommodating measurement error in covariate histories are less standardized. Various methods are available (e.g., [2]) under a classical measurement model (*see **Measurement: Overview***), wherein a measured regression variable is assumed to be the sum of the target variable plus measurement error that is independent, not only of the targeted value but also of other disease risk factors. With such difficult-to-measure exposures as those related to the environment, occupation, physical activity, or diet, a major effort may need to be expended to develop a suitable measurement model and to estimate measurement model parameters in the context of estimating the association between disease rate and the exposure history of interest.

An Example

While there have been many important past and continuing cohort studies over the past several decades, a particular cohort study in which the author is engaged is the Observational Study component of the Women's Health Initiative (WHI) [10, 18]. This study is conducted at 40 Clinical Centers in the United States, and includes 93 676 postmenopausal women in the age range 50–79 at the time of enrollment during 1993–1998. Cohort enrollment took place in conjunction with a companion multifaceted Clinical Trial among 68 133 postmenopausal women in the same age range, and for some purposes the combined Clinical Trial and Observational Study can be viewed as a cohort study in 161 809 women. Most recruitment took place using population-based lists of age- and gender-eligible women living in proximity to a participating Clinical Center.

Postmenopausal hormone use and nutrition are major foci of the WHI, in relation to disease morbidity and mortality. Baseline collection included a personal hormone history interview, a food frequency questionnaire, a blood specimen (for separation and storage), and various risk factor and health-behavior questionnaires. Outcome ascertainment includes periodic structured self-report of a broad range of health outcomes, document collection by a trained outcome specialist, physician adjudication at each Clinical Center, and subsequent centralized adjudication

for selected outcome categories. Exposure data are updated on a regular basis either through questionnaire or clinic visit. To date, the clinical trial has yielded influential, and some surprising, results on the benefits and risks of postmenopausal hormone therapy [17, 19]. The common context and data collection in the Observational Study and Clinical Trial provides a valuable opportunity to compare results on hormone therapy between the two study designs. A major study is currently being implemented using various objective markers of nutrient consumption toward building a suitable measurement model for calibrating the food frequency nutrient assessments and thereby providing reliable information on nutrient-disease associations. A subset of about 1000 Observational Study participants provided replicate data on various exposures at baseline and at 3 years from enrollment toward allowing for measurement error accommodation in exposure and confounding variables.

Concluding Comment

This entry builds substantially on prior cohort study reviews by the author [13, 14], which provide more detail on study design and analysis choices. There are a number of books and review articles devoted to cohort study methods [1, 2, 3, 6, 8, 9, 11, 12, 15, 16].

Coincidences

Consider a group of say r people; the probability that none of the people have a birthday (day and month, but not year) in common is given by the following formidable formula

$$\frac{365 \times 364 \times 363 \cdots \times (365 - r + 1)}{365^r}$$

Applying the formula for various values of r leads to the probabilities shown in Table 1.

The reason for including a group of 23 in the table is that it corresponds to a probability of just under a half. Consequently, the probability that *at least two* of the 23 people share a birthday is a little more than a half (.507). Most people, when asked to guess what size group is needed to achieve greater than a 50% chance that at least two of them share a birthday put the figure much higher than 23.

Birthday matches in a group of people is a simple example of a coincidence, a surprising concurrence of events that are perceived as meaningfully related but have no causal connection. (For other examples, enter ‘coincidences’ into *Google*!). Coincidences that self-styled ‘experts’ attach very low probabilities to (such as UFOs, corn circles, and weeping statues of the Virgin Mary) are all old favorites of the tabloid press. But it is not only *National Enquirer* and *Sun* readers who are fascinated by such occurrences. Even the likes of Arthur Koestler and Carl Jung have given coincidences serious consideration. Jung introduced the term *synchronicity* for what he saw as a causal connecting principle needed to explain coincidences,

arguing that such events occur far more frequently than chance allows. But Jung gets little support from one of the most important twentieth-century statisticians, **Ronald Alymer Fisher** who suggests that ‘the one chance in a million’ will undoubtedly occur, with no less and no more than its appropriate frequency, however surprised we may be that it should occur to us.

Most statisticians would agree with Fisher (a wise policy because he was rarely wrong, and did not take kindly, or respond quietly, to disagreement!) and explain coincidences as due to the ‘law’ of truly large numbers (*see Laws of Large Numbers*). With a large enough sample, any outrageous thing is likely to happen. If, for example, we use a benchmark of ‘one in a million’ to define a surprising coincidence event, then in the United States, with its population of 280 million (2000) we would expect 280 coincidences a day and more than 100 000 such occurrences a year. Extending the argument from a year to a lifetime and from the population of the United States to that of the world (about 6 billion) means that incredibly remarkable events are almost certain to be observed. If they happen to us or to one of our friends, it is hard not to see them as mysterious and strange. But the explanation is not synchronicity, or something even more exotic, it is simply the action of chance.

Between the double-six throw of two dice and the perfect deal at bridge is a range of more or less improbable events that do sometimes happen – individuals *are* struck by lightening, *do* win a big prize in a national lottery, and *do* sometimes shoot a hole-in-one during a round of golf. Somewhere in this range of probabilities are those coincidences that give us an eerie, spine-tingling feeling, such as dreaming of a particular relative for the first time in years and then waking up to find that this person died in the night. Such coincidences are often regarded as weird when they happen to us or to a close friend, but in reality they are not weird, they are simply rare.

Even the most improbable coincidences *probably* result from the play of random events.

Collinearity

Collinearity refers to the intercorrelation among independent variables (or predictors). When more than two independent variables are highly correlated, collinearity is termed *multicollinearity*, but the two terms are interchangeable [4]. Two or more independent variables are said to be collinear when they are perfectly correlated (i.e., $r = -1.0$ or $+1.0$). However, researchers also use the term collinearity when independent variables are highly, yet not perfectly, correlated (e.g., $r > 0.70$), a case formally termed *near collinearity* [4]. Collinearity is generally expressed as the multiple correlation among the i set of independent variables, or R_i^2 .

Perfect collinearity violates the assumption of ordinary least squares regression that there is no perfect correlation between any set of two independent variables [1]. In the context of **multiple linear regression**, perfect collinearity renders regression weights of the collinear independent variables uninterpretable, and near collinearity results in biased parameter estimates and inflated standard errors associated with the parameter estimates [2, 4].

Collinearity is obvious in multiple regression when the parameter estimates differ in magnitude and, possibly, in direction from their respective bivariate correlation and when the standard errors of the estimates are high [4]. More formally, the *variance inflation factor* (VIF) and *tolerance* diagnostics (see **Tolerance and Variance Inflation Factor**)

can help detect the presence of collinearity. VIF_i , reflecting the level of collinearity among an i set of independent variables, is defined as $1 / (1 - R_i^2)$, where R_i^2 is the squared multiple correlations among the i independent variables. A VIF value of 1 indicates no level of collinearity, and values greater than 1 indicate some level of collinearity. Tolerance is defined as $1 - R_i^2$ or $1/VIF$, where values equal to 1 indicate lack of collinearity, and 0 indicates perfect collinearity. Several remedies exist for reducing or eliminating the problems associated with collinearity, including dropping one or more collinear predictors, combining collinear predictors into a single composite, and employing ridge regression or principle components regression (see **Principal Component Analysis**) (e.g., [3]).

Combinatorics for Categorical Variables

Categorical Variables

Datasets gathered in the behavioral, social, and biomedical sciences using survey instruments tend to consist of categorical responses. In a survey, the response can vary from individual to individual, for example, the question, ‘Have you smoked a cigarette during the past week?’ may be answered using one of the three following responses ‘Yes’, ‘No’, ‘Can’t remember’. The responses are mutually exclusive, that is, each response belongs to only one of the three response categories. It is also referred to in the literature as a nominal variable because the response categories have labels (names) that lack an intrinsic order (see **Scales of Measurement**). Formally, a categorical or nominal variable is defined as a variable that has two or more mutually exclusive groups (or categories) that lack an intrinsic order. An example of a variable that does not have mutually exclusive categories is the psychiatric classification of diagnosis: neurotic, manic-depressive, schizophrenic, and other disorders. An individual could have more than one diagnosis, that is, have co-occurring mental disorders.

Sometimes, a categorical response may be ordered, for example, socioeconomic status may be grouped into ‘low’, ‘medium’, and ‘high’. In this case, the categorical variable is referred to as an *ordinal variable*. Thus, a categorical variable may be either nominal or ordinal. In the social and behavioral sciences, self-report of behavior is typically gathered using an ordinal scale ranging from 1 through 5, with response 1 for ‘never’, 2 for ‘rarely’, 3 for ‘sometimes’, 4 for ‘often’, and 5 representing ‘always’. This illustrates how a numerical structure can be imposed on an ordinal variable, that is, the responses can be mapped onto a numerical scale permitting one to perform numerical operations such as addition and obtain statistics such as the arithmetic mean and standard deviation.

A dichotomous categorical variable is defined as a variable with only two possible responses or outcomes, for example, Yes or No, or 0 or 1. A dichotomous variable is also called a *binomial variable*, for example, gender is a binomial variable. A categorical variable with more than two responses is called

a *multinomial variable*. Marital status is a multinomial variable as the response may be ‘Married’, ‘Separated’, ‘Divorced’, or ‘Single’. A multinomial variable is also referred to as a *polytomous variable*. The ordinal variable with responses mapped onto the numbers 1 through 5 is an example of an ordered polytomous variable.

Data is gathered to test study hypothesis or lend credence to theories, for example, are there more females with internalizing behavioral problems than males in the population? The question can be answered using the counts of males and females in the study sample with/without internalizing behavior problems and reporting the percentages as estimates for the males or females in the population.

Probability and Counting Rules

Probability is defined as the likelihood or chance that a particular response will be given, for example, the chance that the next sampled individual is male. In empirical classical probability, the probability is defined as the ratio of the number of male individuals in the sample to the total number of individuals sampled. This differs from the *a priori* classical definition of probability in that it assumes no *a priori* knowledge of the populations. The *a priori* classical probability is the ratio of the total number of males in the population to the total population. In the social and behavioral sciences, the empirical classical probability is used to estimate and make inferences about population characteristics in the absence of *a priori* knowledge.

Notice that in the definition of probability, one is counting the number of times the desired response, for example, male, is observed. Counting rules come in handy for circumstances where it is not feasible to list all possible ways in which a desired response might be obtained.

Suppose an individual is randomly selected from the population and the gender of the individual noted. This process is repeated 10 times. How would we determine the number of different possible responses, that is, the sequences of males and females?

Counting Rule 1. If any one of k mutually exclusive responses are possible at each of n trials, then the number of possible outcomes is equal to k^n .

Using rule 1 suggests that there are $2^{10} = 1024$ possible sequences of males and females.

2 Combinatorics for Categorical Variables

The second counting rule involves the computation of the number of ways that a set of responses can be arranged in order. Suppose that there are six patients requesting an appointment to see their psychiatrist. What are the total number of ways in which the receptionist may schedule them to see the psychiatrist on the same day?

Counting Rule 2. The number of ways in which n responses can be arranged in order is given by $n! = n(n-1)(n-2)\dots(3)(2)(1)$, where $n!$ is called n factorial and $0!$ is defined to be 1.

An application of Rule 2 shows that the receptionist has $6! = (6)(5)(4)(3)(2)(1) = 720$ ways to schedule them.

But if the psychiatrist can only see 4 patients on that day, in how many ways can the receptionist schedule them in order?

Counting Rule 3. The number of arrangements for k responses selected from n responses in order is $n!/(n-k)!$. This is called the rule of permutations.

Using the rule of permutations, the receptionist has

$$\frac{6!}{(6-4)!} = \frac{(6)(5)(4)(3)(2)(1)}{(2)(1)} = 360 \text{ ways.} \quad (1)$$

But what if the receptionist is not interested in the order but only in the number of ways that any 4 of the 6 patients can be scheduled?

Counting Rule 4. The number of ways in which k responses can be selected from n responses is $n!/k!(n-k)!$. This is called the rule of combinations and the expression is commonly denoted by $\binom{n}{k}$.

The combinations counting rule shows that the receptionist has

$$\frac{6!}{4!(6-4)!} = \frac{6!}{4!2!} = \frac{(6)(5)(4)(3)(2)(1)}{(4)(3)(2)(1)(2)(1)} = 15 \text{ ways.} \quad (2)$$

The main difference between a permutation and a combination is that in the former the order in which

the first four patients out of six call in are each considered distinct, while in the latter the order of the first four is not maintained, that is, the four that call in are considered as the set of individuals that get the appointment for the same day but are not necessarily scheduled in the order they called in.

Example Suppose that a receptionist schedules a total of k patients over n distinct days. What is the probability that t patients are scheduled on a specific day?

First, an application of counting rule 4 to determine the number of ways t patients can be selected out of k gives $\binom{k}{t}$ total ways for choosing $t = 0, 1, 2, \dots, k$ patients scheduled on a specific day. Using counting rule 1, one can compute that the remaining $(k-t)$ patients can be scheduled over the remaining $(n-1)$ ways in a total of $(n-1)^{k-t}$ possible ways.

There are a total of n^k possible ways of randomly scheduling k patients over n days using counting rule 1.

The empirical probability that t patients

are scheduled on a specific day

$$\begin{aligned} & \text{number of ways of scheduling } t \text{ of} \\ & \quad k \text{ people on a specific day} \\ &= \frac{\text{number of ways of scheduling}}{k \text{ people on } n \text{ days}} \\ &= \frac{\binom{k}{t} (n-1)^{k-t}}{n^k}. \end{aligned} \quad (3)$$

This last expression can be rewritten as $\binom{k}{t} (1/n^t) (1 - (1/n))^{k-t}$, which is the empirical form of the binomial distribution.

Common Pathway Model

The common pathway model, as applied to genetically sensitive data, is a multivariate model in which the covariation between a group of variables is controlled by a single phenotypic latent factor (*see Latent Variable*), with direct paths to each variable [2]. This intermediate factor itself is influenced by genetic and environmental latent factors. The term ‘common’ refers to the fact that the effects of the genetic and environmental factors on all observed variables will impact via this single factor. Because the phenotypic latent factor has no scale, the E_c path (residual variance) is fixed to unity to make the model identified. There is also a set of specific genetic and environmental factors accounting for residual, variable specific variances (see Figure 1). For these specific factors to all have free loadings, the minimal number of variables in this model is three.

For twin data, two identical common pathway models are modeled for each twin with the genetic and environmental factors across twins (both common

and specific) connected by the expected correlations, 1 for MZ twins, 0.5 for DZ twins (see Figure 1).

Similar to the *univariate genetic model*, the MZ and DZ ratio of the cross-twin within variable correlations (e.g., Twin 1 variable 1 and Twin 2 variable 1) will indicate the relative importance of genetic and environmental variance components for each variable. On the other hand, the MZ and DZ ratio of the cross-twin cross-trait correlations (e.g., Twin 1 variable 1 and Twin 2 variable 2) will determine the relative importance of genetic and environmental factors in the covariance between variables (i.e., genetic and environmental correlations). In addition, for any two variables it is possible to derive the part of the phenotypic correlation determined by common genes (which will be a function of both their h^2 (*see Heritability*) and genetic correlation) and by common shared and unique environmental effects (which will be a function of their c^2 and e^2 , and the C and E correlation). For more information on genetic and environmental correlations between variables, see the general section on **multivariate genetic analysis**. Parameter estimates are estimated from the observed

Figure 1 Common pathway model: A_c , C_c , and E_c are the common additive genetic, common shared, and common nonshared environmental factors, respectively. L_{ph} is the latent intermediate phenotypic variable, which influences all observed variables. The factors at the bottom are estimating the variable specific A and E influences. For simplicity, the specific C factors were omitted from the diagram

2 Common Pathway Model

variances and covariances by fitting **structural equation models**. The common pathway model is more parsimonious than the independent pathway model because it estimates fewer parameters.

So what is the meaning and interpretation of this factor model? The common pathway model is a more stringent model than the **independent pathway model**. It hypothesizes that covariation between variables arises purely from their phenotypic relation with the latent intermediate variable. This factor is identical to the factor derived from higher order phenotypic factor analyses, with the additional possibility to estimate the relative importance of genetic and environmental effects of this factor. In contrast, in the independent pathway model, where the common genetic and environmental factors influence the observed variables directly, different clusters of variables for the genetic and environmental factors are possible. This means that some variables could be specified to covary mainly because of shared genetic effects, whereas others covary because of shared environmental effects.

An obvious application of this model is to examine the etiology of **comorbidity**. In an adolescent twin sample recruited through the Colorado Twin Registry and the Colorado Longitudinal Twin Study, conduct disorder and attention deficit hyperactivity disorder, along with a measure of substance experimentation and novelty seeking, were used as indices of a latent *behavioral disinhibition* trait. A common pathway model evaluating the genetic and environmental architecture of this latent phenotype suggested that behavioral disinhibition is highly heritable (0.84), and is not influenced significantly by shared environmental factors. These results suggest that a variety of

adolescent problem behaviors may share a common underlying genetic risk [3].

Another application of this model is to determine the variation in a behavior that is agreed upon by multiple informants. An example of such an application is illustrated for antisocial behavior in 5-year-old twins as reported by mothers, teachers, examiners, and the children themselves [1]. Problem behavior ascertained by consensus among raters in multiple settings indexes cases of problem behavior that are pervasive. Heritability of this pervasive antisocial behavior was higher than any of the informants individually (which can be conceptualized as situational antisocial behavior). In addition, significant informant specific unique environment (including) measurement error was observed.

Community Intervention Studies

Introduction

Community intervention trials are an example of the broader class of studies called *group-randomized trials* (GRTs), in which investigators randomize identifiable groups to conditions and observe members of those groups to assess the effects of an intervention [5]. Just as the familiar randomized clinical trial is the gold standard when randomization of individuals to study conditions is possible, the GRT is the gold standard when **randomization** of identifiable groups is required. That situation exists for community-based interventions, which typically operate at a group level, manipulate the social or physical environment, or cannot be delivered to individuals.

An Example

The Tobacco Policy Options for Prevention study was a community intervention trial designed to test the effects of changes in local policies to limit youth access to tobacco [3]. After stratifying on population size and baseline adolescent smoking rate, 14 communities were randomized to the intervention or control condition. The 32-month intervention was designed to change local ordinances to restrict youth access to tobacco, to change retailers' practices regarding provision of tobacco to youth, and to increase enforcement of tobacco age-of-sale laws. Data were collected from students in grades 8–10 and from purchase attempt surveys at retail outlets, both before the intervention and three years later. Daily smoking was reduced by one-third and students reported significantly lower availability of tobacco products from commercial sources [3].

Distinguishing Characteristics

Four characteristics distinguish the GRT [5]. First, the unit of assignment is an identifiable group. Second, different groups are assigned to each condition, creating a nested or hierarchical structure. Third, the units of observation are members of those groups so

that they are nested within both their condition and their group. Fourth, there usually is only a limited number of groups assigned to each condition.

These characteristics create several problems for the design and analysis of GRTs. The major design problem is that a limited number of often-heterogeneous groups makes it difficult for randomization to distribute potential sources of confounding evenly in any single realization of the experiment. This increases the need to employ design strategies that will limit confounding and analytic strategies to deal with confounding where it is detected. The major analytic problem is that there is an expectation for positive **intraclass correlation (ICC)** among observations on members of the same group [4]. That ICC reflects an extra component of variance attributable to the group above and beyond the variance attributable to its members. This extra variation will increase the variance of any group-level statistic beyond what would be expected with random assignment of members to conditions. With a limited number of groups, the degrees of freedom (df) available to estimate group-level statistics are limited. Any test that ignores either the extra variation or the limited df will have an inflated Type I error rate [1].

Potential Design and Analysis Problems and Methods to Avoid Them

For GRTs, there are four sources of bias that should be considered during the planning phase: selection, differential history, differential maturation, and contamination (*see Quasi-experimental Designs*). The first three are particularly problematic in GRTs where the number of units available for randomization is often small. GRTs planned with fewer than 20 groups per condition would be well served to include careful matching or **stratification** prior to randomization to help avoid these biases. Analytic strategies, such as regression adjustment for confounders, can be very helpful in dealing with any bias observed after randomization (*see Regression Models*).

There are two major threats to the validity of the analysis of a GRT, which should be considered during the planning phase: misspecification of the analytic model and low **power**. Misspecification of the analytic model most commonly occurs when the investigator fails to reflect the expected ICC in the analytic model. Low power most commonly occurs

when the design is based on an insufficient number of groups randomized to each condition.

There are several analytic approaches that can provide a valid analysis for GRTs [2, 5]. In most, the intervention effect is defined as a function of a condition-level statistic (e.g., difference in means, rates, or slopes) and assessed against the variation in the corresponding group-level statistic. These approaches included mixed-model ANOVA/ANCOVA for designs having only one or two time intervals (*see Linear Multilevel Models*), random coefficient models for designs having three or more time intervals, and **randomization tests** as an alternative to the model-based methods. Other approaches are generally regarded as invalid for GRTs because they ignore or misrepresent a source of random variation. These include analyses that assess condition variation against individual variation and ignore the group, analyses that assess condition variation against individual variation and include the group as a fixed effect, analyses that assess the condition variation against subgroup variation, and analyses that assess condition variation against the wrong type of group variation. Still other strategies may have limited application for GRTs. For example, the application of **generalized estimating equations (GEE)** and the sandwich method for standard errors requires a total of 40 or more groups in the study, or a correction for the downward bias in the sandwich estimator for standard errors when there are fewer than 40 groups [7].

To avoid low power, investigators should plan a large enough study to ensure sufficient replication, employ more and smaller groups instead of a few large groups, employ strong interventions with a good reach, and maintain the reliability of intervention implementation. In the analysis, investigators should consider regression adjustment for covariates, model time if possible, and consider post hoc stratification.

Excellent treatments on power for GRTs exist, and the interested reader is referred to those sources for additional information. Chapter 9 in the Murray text provides perhaps the most comprehensive treatment of detectable difference, sample size, and power for GRTs [5]. Even so, a few points are repeated here. First, the increase in between-group variance due to the ICC in the simplest analysis is calculated as $1 + (m - 1)ICC$, where m is the number of members per group; as such, ignoring even a small ICC can underestimate standard errors if m is large. Second,

more power is available given more groups per condition with fewer members measured per group than given just a few groups per condition with many members measured per group, no matter the size of the ICC. Third, the two factors that largely determine power in any GRT are the ICC and the number of groups per condition. For these reasons, there is no substitute for a good estimate of the ICC for the primary endpoint, the target population, and the primary analysis planned for the trial, and it is unusual for a GRT to have adequate power with fewer than 8–10 groups per condition. Finally, the formula for the standard error for the intervention effect depends on the primary analysis planned for the trial, and investigators should take care to calculate that standard error, and power, based on that analysis.

Comorbidity

Comorbidity is the potential co-occurrence of two disorders in the same individual, family etc. According to epidemiological studies (e.g., [9, 17]), comorbidity between psychiatric disorders often exceeds the rate expected by chance alone. Increased knowledge regarding the causes of comorbidity between two psychiatric disorders may have a significant impact on research regarding the classification, treatment, and etiology of both disorders. Therefore, several researchers have proposed alternative models explaining the etiology of comorbidity (e.g., [1, 2, 5], and [16]), and ways to discriminate the correct explanation for comorbidity between two or more alternatives (e.g., [7, 8], and [10]). To date, Klein and Riso have presented the most comprehensive set of alternative comorbidity models, and Neale and Kendler presented the quantitative specifications of Klein and Riso's models (see Table 1). In a series of studies, we examined the validity of common methods used to test alternative comorbidity models [11–14].

Common Methods Used to Test Alternative Comorbidity Models

Klein and Riso's Family Prevalence Analyses.

For each comorbidity model, Klein & Riso [7] presented a set of predictions regarding the prevalence of disorders in the relatives of different groups of probands. They presented a comprehensive set of predictions comparing the prevalence of disorder A-only, disorder B-only, and disorder AB (i.e., both disorders) among the relatives of probands with A-only, B-only, AB, and controls. Several studies have used these predictions to test alternative comorbidity models (e.g., [6, 15], and [18]).

Family Prevalence Analyses in the Literature. Many other researchers (e.g., [3] and [4]) have conducted a subset of the Klein and Riso analyses or analyses very similar to those presented by Klein and Riso [7] without testing their comprehensive set of predictions. Most of the studies in the literature have focused on three comorbidity models, (a) the alternate forms model (i.e., the two comorbid disorders are

alternate manifestations of the same underlying liability), (b) the correlated liabilities model (i.e., there is a significant correlation between the liabilities for the two models), and (c) the three independent disorders model (i.e., the comorbid disorder is a third disorder that is etiologically distinct from either disorder occurring alone).

Neale and Kendler Model-fitting Approach.

Neale and Kendler [8] described 13 alternative models. They illustrated the probabilities for the four combinations of disease state ((a) neither A nor B; (b) A but not B; (c) B but not A; (d) both A and B) for each comorbidity model, then illustrated the probabilities for the 10 combinations of the affected or unaffected status for pairs of relatives for each comorbidity model (e.g., neither A nor B in relative 1 and neither A nor B in relative 2; both A and B in relative 1 and A only in relative 2, etc.). The data that are analyzed in the Neale and Kendler model-fitting approach is simply the frequency tables for the number of relative pairs in each possible combination of a disease state. The observed cell frequencies are compared with the expected cell frequencies (i.e., the probabilities for the 10 combinations of the affected or unaffected status for pairs of relatives) in each comorbidity model. The comorbidity model with the smallest difference between the observed cell frequencies and the expected cell frequencies is chosen as the best fitting model.

Underlying Deficits Approach.

Several researchers have tested alternative comorbidities by comparing the level of underlying deficits of the two comorbid disorders in individuals with neither disorder, A only, B only, and both A and B. For example, Pennington, Groisser, and Welsh [10] examined the comorbidity between reading disability and attention deficit hyperactivity disorder (ADHD), comparing the underlying deficits associated with reading disability (i.e., phonological processes) and the underlying deficits associated with ADHD (i.e., executive functioning) in individuals with neither disorder, reading disability only, ADHD only, and both reading disability and ADHD. Most of the researchers using this approach have made predictions for 5 of the 13 Neale and Kendler comorbidity models. In addition to the three models often tested using family prevalence analyses in the literature (i.e., alternate forms, correlated liabilities, and three independent disorders),

2 Comorbidity

Table 1 Description of the Neale and Kendler models

Name	Abbreviation	Description
Chance	CH	Comorbidity is due to chance.
Alternate forms	AF	Two disorders are alternate manifestations of a single liability.
Random multiformity	RM	Being affected by one disorder directly increases the risk for having the other disorder. (Individuals with disorder A have risk of disorder B increased by probability p and individuals with disorder B have risk of disorder A increased by probability r .)
Random multiformity of A	RMA	Submodel of RM where r is 0.
Random multiformity of B	RMB	Submodel of RM where p is 0.
Extreme multiformity	EM	Being affected by one disorder directly increases the risk for having the other disorder. (Individuals with disorder A have disorder B if they surpass a higher threshold on the liability for disorder A and individuals with disorder B have disorder A if they surpass a higher threshold on the liability for disorder B.)
Extreme multiformity of A	EMA	Submodel of EM where there is no second, higher threshold on the liability for disorder B.
Extreme multiformity of B	EMB	Submodel of EM where there is no second, higher threshold on the liability for disorder A.
Three independent disorders	TD	The comorbid disorder is a disorder separate from either disorder occurring alone.
Correlated liabilities	CL	Risk factors for the two disorders are correlated.
A causes B	ACB	A causes B.
B causes A	BCA	B causes A.
Reciprocal causation	RC	A and B cause each other.

researchers have made predictions regarding the random multiformity of A or random multiformity of B models (i.e., an individual who has one disorder is at an increased risk for having the second disorder, although he or she may not have an elevated liability for the second disorder).

Simulations

In all studies, simulations were conducted to test the validity of the common methods used to test alternative comorbidity models. Data were simulated for each of the 13 Neale and Kendler comorbidity models. In these simulated data, the true cause of comorbidity is known. Then, analyses commonly used to test the alternative comorbidity models were conducted on each of the 13 simulated datasets. If a particular analysis is valid, the predicted result should be found in the data simulated for the comorbidity model, and the predicted result should not be found

in data simulated for other comorbidity models (i.e., the particular analysis should discriminate a particular comorbidity model from alternative hypotheses).

Description of the Results

Klein and Riso's Family Prevalence Analyses.

Most of Klein and Riso's predictions were validated by the simulation results, in that most of their predicted results matched the results in the simulated datasets. However, there were several notable differences between the predicted results and results obtained in the simulated datasets. Some of Klein and Riso's predictions were not obtained in the simulated results because of lack of power in the simulated datasets. Another reason for the discrepancy between the predicted results and the results in the simulated dataset was the predictions' lack of consideration of all possible pathways for the comorbid disorder,

notably the fact that there will be some individuals who have both disorders A and B due to chance.

Family Prevalence Analyses in the Literature. The results of the study examining the validity of family prevalence analyses found in the literature indicate that most of these analyses were not valid. There are some analyses that validly discriminate the alternate forms model from alternative models, but none of the analyses testing the correlated liabilities model and the three independent disorders model were valid. In general, these analyses did not consider the fact that although the predicted results may be consistent with a particular comorbidity model, they also may be consistent with several alternative comorbidity models.

Neale and Kendler Model-fitting Approach. In general, the Neale and Kendler model-fitting approach discriminated the following classes of models reliably: the alternate forms model, the random multiformity models (i.e., random multiformity, random multiformity of A, and random multiformity of B), the extreme multiformity models (i.e., extreme multiformity, extreme multiformity of A, and extreme multiformity of B), the three independent disorders model, and the correlated liabilities models (i.e., correlated liabilities, A causes B, B causes A, and the reciprocal causation). Discrimination within these classes of models was poorer. Results from simulations varying the **prevalences** of the comorbid disorders indicate that the ability to discriminate between models becomes poorer as the prevalence of the disorders decreases, and suggests the importance of considering the issue of **power** when conducting these analyses.

Underlying Deficits Approach. Given adequate power, the method of examining the underlying deficits of comorbid disorders can distinguish between all 13 Neale and Kendler comorbidity models, except the random multiformity, extreme multiformity, and three independent disorders models. As the sample sizes decreased and the magnitude of correlation between the underlying deficits and the symptom scores decreased, the ability to discriminate the correct comorbidity model from alternative hypotheses decreased. Again, the issue of power should be considered carefully.

Conclusions

In a series of simulation studies, we examined the validity of common methods used to test alternative comorbidity models. Although most of Klein and Riso's family prevalence analyses were valid, there were notable discrepancies between their predicted results and results found in the simulated datasets. Some of the family prevalence analyses found in the literature were valid predictors of the alternate forms model, but none were valid predictors of the correlated liabilities or three independent disorders models. The Neale and Kendler model-fitting approach and the method of examining the underlying deficits of comorbid disorders discriminated between several comorbidity models reliably, suggesting that these two methods may be the most useful methods found in the literature. Especially encouraging is the fact that some of the models that cannot be distinguished well using the Neale and Kendler model-fitting approach can be distinguished well by examining the underlying deficits of comorbid disorders, and vice versa. The best approach may be a combination of these two methods.

Compensatory Equalization

Compensatory equalization refers to a phenomenon in intervention studies (*see* **Clinical Trials and Intervention Studies**) in which comparison groups not obtaining the preferred treatment are provided with compensations that make the comparison groups more equal than originally planned [1, 4]. The simplest case would be an intervention study with a treatment group and a no-treatment control group, in which the people in charge of the intervention program feel the control group is unfairly withheld from a beneficial treatment and provide alternative goods and services to the participants in that control group. The implication is that the difference between the outcomes on a posttest is not a reflection of the difference between the treatment group and the original control group, but rather of the difference between the experimental group and the ‘control + alternative goods and services’ group.

Instead of adding benefits to the control group, compensatory equalization can also result from removing beneficial ingredients from the favored treatment group for reasons of perceived unfairness. This has been called *compensatory deprivation* but because the net effect is the same (*viz.*, equalization), it can be looked upon as a mere variation on the same theme.

Compensatory equalization was first introduced by Cook and Campbell [1] and listed among their threats to **internal validity** (*see* **Quasi-experimental Designs**). However, Shadish, Cook, and Campbell [4] rightly classified this confounder among the threats to construct validity. Internal validity threats are disturbing factors, that can occur even without a treatment, while compensatory equalization is intimately related to the treatment. In fact, compensatory equalization occurs *because* a treatment was introduced and should be considered as an integral part of the conceptual structure of the treatment contrast. This immediately suggests an obvious way of dealing with this confounder: the compensations must be included as part of the treatment construct description [4].

Just like in **compensatory rivalry** and **resentful demoralization** in compensatory equalization as

well, the participants themselves may be the instigators of the bias. This happens if some participants have the impression that they have been put at a disadvantage and force the researchers, the administrators, or the program staff to deliver compensations. Unlike these two other threats to construct validity, however, the involvement of people responsible for the treatment administration (e.g., therapists or teachers) or of external goods and services is crucial. Notice also that these threats to construct validity cannot be ruled out or made implausible by resorting to random assignment of participants to the comparison groups. Because the social comparison during the study itself is the source of the distortion, compensatory equalization may be present in both randomized and nonrandomized studies.

An actual research example of compensatory equalization can be found in Birmingham’s Homeless Project in which standard day care for homeless persons with substance abuse problems was compared with an enhanced day treatment condition [3]. Service providers complained about the inequity that was installed and put additional services at the disposal of the people in the standard day care group. In this way, the outcome for the two groups became more similar than would have been if no additional services were provided.

Researchers who want to avoid or minimize the problem of compensatory equalization might try to isolate the comparison groups in time or space, or make participants or service providers unaware of the intervention being applied (like in double-blind clinical trials). Another strategy, which might be used in combination with these isolation techniques, is to instruct the service providers about the importance of treatment integrity, or more fundamentally, not to use any conditions that can be perceived as unfair. If lack of treatment integrity is suspected, then interviews with the service providers and the participants are of paramount importance. Statistical correction and **sensitivity analysis** [2] might be worth considering, but if major and systematic compensations are blatantly interfering with treatment implementation, it may be more prudent to admit a straight change in the treatment construct itself.

Compensatory Rivalry

Compensatory rivalry is a potential threat to construct validity of the cause in intervention studies (*see Validity Theory and Applications*) [1, 3, 5]. Put more plainly, the causal construct of interest (i.e., intervention) is given to the experimental group, and not to the control group. However, the control group, contrary to the intention of investigators, obtains it. Although it is more likely a potential threat in experimental studies where subjects are randomly assigned to groups, it can operate in quasi-experimental studies as well (e.g., pretest–post–test *see Nonequivalent Group Design*). We limit our discussion to the true experiment.

Compensatory rivalry usually occurs when the study group that is not assigned the experimental treatment feels disadvantaged, disappointed, or left out and decides to obtain a similar intervention on its own. Of course, if the control group receives the intervention, this distorts the construct of ‘control group’ and investigators lose the logic for inferring the cause of the outcomes that are observed.

This threat is sometimes referred to as the *John Henry effect*, named after the legendary railroad worker who died after competing successfully with a steam drill because it threatened his and fellow workers’ jobs [4]. However, it may or may not involve intentional competition or rivalry with the experimental group. Control subjects may simply want to achieve the desirable outcome without regard to comparisons with experimental subjects. However, if something is at stake for the control group relative to the experimental group, then manipulation of the treatment or even of the outcome variable may be of concern. In the case of John Henry, a super performance by an extraordinary individual gave the appearance of successful competition by the control group. In some cases, members of the control group may find other ways to manipulate the outcome, (e.g., **cheating**).

To understand the threat of compensatory rivalry, consider the typical study hypothesis for experimental designs. In the true experiment with random assignment to groups, the groups are assumed to be equivalent on all variables except on exposure to the treatment. In this case, we expect that any differences observed on the posttest outcome measure to

be due to the treatment. We do not want the control group to seek out the treatment on its own since this would reduce the likelihood of us observing a treatment effect if there were one.

Consider as an example an experimental nutrition intervention study to examine the effect of a weight reduction program on obese school aged children. Those students assigned to the control group may be motivated to begin a nutrition program and, along with their parents, may seek out alternative programs. With an outcome measure of lean body mass, for example, the differences observed between the student groups would be lessened because of the alternative independent services received by the control group, and the effectiveness of the treatment would thus be masked.

While we are not likely to prevent compensatory rivalry from operating, we should be aware of its possibility, measure it, and if possible, statistically adjust for it. Minimally, we would want to consider its possibility in interpreting the study findings. Although not a foolproof solution, researchers may consider the use of a delayed-treatment design to minimize the problem of compensatory rivalry. In a delayed-treatment design, the control group waits to receive the treatment until after the experimental group receives it. In the delayed-treatment design, we would measure both groups at baseline, again after the experimental group received the intervention, and then again after the delayed-treatment group received the intervention. For example, in an attempt to minimize compensatory rivalry in a firefighter physical fitness intervention program, a delayed-treatment design was implemented [2]. Even though everyone would eventually receive the program, firefighters in the delayed-treatment group expressed disappointment in not being able to start the program right away. The investigators asked the firefighters in the delayed-treatment group to keep an exercise log while waiting to begin the fitness program. In this way, their self-reported physical activity could be adjusted for in the statistical analyses of program effects. Compensatory rivalry, like other potential threats to the validity of study conclusions, merits our constant vigilance.

Completely Randomized Design

The completely randomized design (CRD) is the most basic type of **experimental design**. As such, it forms the basis for many more complex designs. Nevertheless, it is important in its own right because it is one of the most prevalent experimental designs, not just in the behavioral sciences but also in a wide range of other disciplines. A primary reason for the popularity of this design in addition to its simplicity is that random assignment to treatment conditions provides a strong basis for causal inference. **Sir Ronald A. Fisher** is usually credited with this insight and for developing the foundations of the CRD.

The CRD can be thought of as any design where each individual is randomly assigned to one of two or more conditions, such that the probability of being assigned to any specific condition is the same for each individual. There is no requirement that this probability be the same for every condition. For example, with three conditions, the probabilities of assignment could be .50, .25, and .25 for groups 1, 2, and 3 respectively. From a statistical perspective, there are usually advantages to keeping these probabilities equal, but there are sometimes other considerations that favor unequal probabilities [3].

The CRD is very flexible in that the conditions can differ either qualitatively or quantitatively. The conditions can also differ along a single dimension or multiple dimensions (although in the latter case, the design will typically be conceptualized as a factorial design). In the simplest case, only a single response variable (i.e., dependent variable) is measured for each person, but the design also allows multiple dependent variables.

Data from the CRD are typically analyzed with **analysis of variance (ANOVA)** or **multivariate analysis of variance (MANOVA)** in the case of more than one dependent variable. A standard *F* test can be used to test a null hypothesis that the population means of all groups are equal to one another. Tests of comparisons (i.e., contrasts) (*see Multiple Comparison Procedures*) provide an adjunct to this omnibus *F* test in designs with more than two groups. Statistical tests should frequently be accompanied by

measures of **effect size** which include measures of proportion of explained variance as well as **confidence intervals** for mean differences. Experimental design texts [1, 2] provide further details of data analysis for the CRD.

Recent years have seen increased attention paid to planning an appropriate sample size in the CRD [1, 2]. An adequate sample size is important to achieve acceptable statistical **power** to reject the null hypothesis when it is false and to obtain sufficiently narrow confidence intervals for comparisons of mean differences. In fact, the single biggest disadvantage of the CRD is arguably that it often requires a very large sample size to achieve adequate power and precision. For example, even in the simple case of only 2 groups of equal size and an alpha level of 0.05 (two-tailed), a total sample size of 128 is necessary in order to have a 0.80 probability of detecting a medium effect size. The reason such large sample sizes are often needed is because all sources that make a specific person's score different from the mean score in that person's group are regarded as errors in the ANOVA model accompanying a CRD. This reflects the fact that the CRD relies exclusively on randomization of all relevant influences on the dependent variable instead of attempting to control for these influences. As a consequence, the error variance in the ANOVA associated with the CRD is frequently large, lowering power and precision. Primarily for this reason, more complex designs and analyses such as the **randomized block design** and **analysis of covariance** have been developed to control for extraneous influences and thus increase power and precision.

Computational Models

The Nature of Computational Models

Computational modeling involves developing a set of interrelated mathematical, logical, and statistical propositions to simulate behavior and mimic real-world phenomena [7, 15]. By developing a series of ‘if-then’ statements, modelers can create algorithms that predict certain levels of an output, given specified levels of an input (e.g., *if* unemployment exceeds ‘25%’, *then* we will experience a recession by the year ‘2010’). This technique, shown to be effective in fields such as biology, meteorology, and physics, is slowly being adopted by behavioral scientists. Because of its ability to simulate dynamic, complex, and stochastic phenomena, computational modeling has been touted as the ‘third scientific research discipline’ [7].

To build computational models, Whicker and Sigelman [13] advise that five elements be considered: assumptions, parameters, inputs, outputs, and algorithms. First, the modeler must make a number of assumptions, which, in effect, are the compromises a modeler must make for his/her simulation to work. Among these is the assumption that the model being developed is indeed similar to the behavioral processes people actually experience. Next, the modeler must decide which variables will be examined and manipulated (inputs), which variables will be held constant (parameters), and how inputs will affect the phenomena of interest (outputs). Computational modeling involves using these inputs and outputs to develop a series of if-then statements (algorithms), based on theory and previous empirical research [7]. Essentially, the modeler specifies a number of theory-based environmental and individual conditions that may impact the phenomenon of interest. Once these algorithms are developed, numbers are generated from programs such as Basic, SAS, or SPSS that test the specified relationships. Cognitive psychologists have also developed their own software (e.g., Adaptive Character of Thought Theory, ACT-R) that reflects the underlying theory [2, 3].

Given the degree of control and theoretical rigor, computational modeling is a technique that can greatly inform research and practice. There are a number of benefits to using computational modeling [15]. First, computational modeling allows the

researcher to examine phenomena impossible to study in most field or laboratory settings. For instance, cross-sectional and even many longitudinal studies (which usually span a limited time frame) fall short of fully explaining processes over long periods of time. Second, computational modeling affords the researcher with a high level of precision and control, ensuring that extraneous factors do not affect outcomes. As mentioned, researchers decide which parameters will be fixed and which variables/inputs will be manipulated in each model. Third, computational modeling can effectively handle and model the inherent nesting of individuals within work groups and organizations [6]. Finally, computational modeling is of greatest benefit when grounded in theory and preexisting research. By utilizing established research, computational models can more precisely estimate the magnitude and form (i.e., linear, curvilinear) of the relationship between variables.

Previous research has used modeling techniques to examine phenomena such as the consequences of withdrawal behavior [4] and the impact of faking on personality tests [14]. In this first example, Hanisch et al. [4] used a computer simulation (WORKER) that reproduced a ‘virtual organization’, thus allowing them to test how various organizational and individual factors influenced different withdrawal behaviors, and how these effects may change over time. Ployhart and Ehrhart [10] modeled how racial subgroup differences in test-taking motivation contribute to subgroup test score differences. Cognitive psychologists, such as Anderson [2, 3], have used ACT-R to model human cognition; and in particular, have modeled how humans acquire procedural and declarative knowledge and the acquisition of problem-solving and decision-making skills.

Monte Carlo simulations are a specific type of computational model. Here, the focus is on understanding the characteristics of a statistic (e.g., bias, efficiency, consistency), often under real-world situations or conditions where the assumptions of the statistic are violated. For example, research has examined how various fit indices are affected by model misspecification, for example [5]. Likewise, we may want to understand the accuracy of formula-based cross-validity estimates when there is preselection on the predictors [12]. There have been a wealth of studies examining such issues, and much of what we know about the characteristics of statistics is based on large-scale Monte Carlo studies.

An increasingly common computational model is a hybrid between statistical and substantive questions. This type of model is frequently used when we want to understand the characteristics of a statistic to answer important applied questions. For example, we may want to know the consequences of error variance heterogeneity on tests of differences in slopes between demographic subgroups [1]. LeBreton, Ployhart, and Ladd [8] examined which type of predictor relative importance estimate is most effective in determining which predictors to keep in a regression model. Sackett and Roth [11] demonstrated the effects on adverse impact when combining predictors with differing degrees of intercorrelations and subgroup differences. Murphy [9] documented the negative effect on test utility when the top applicant rejects a job offer. In each of these examples, a merging of substantive and statistical questions has led to a simulation methodology that informs research and practice. The power of computational modeling in such circumstances helps test theories and develop applied solutions without the difficulty, expensive, and frequent impossibility of collecting real-world data.

Computer-Adaptive Testing

The phrase *computer-adaptive testing* (CAT) describes a wide range of tests administered on a computer, where the test difficulty is specifically targeted to match the proficiency of each examinee or where items are selected to provide an accurate pass/fail or mastery decision using as few items as possible. Applications of CAT can be found for achievement or performance assessments, aptitude tests, certification tests, and licensure tests. Unlike conventional, standardized, paper-and-pencil tests, where all examinees receive a common test form or test battery comprising the same items, in CAT, each examinee may receive a different assortment of items selected according to various rules, goals, or procedures.

There are numerous examples of successful, large-scale CAT testing programs such as the ACCU-PLACER postsecondary placement exams, operated by the College Board [5], the Graduate Record Exam [6], the Armed Service Vocational Aptitude Battery [16], and several licensure or certification tests such as the Novell certification exams and the licensure exam for registered nurses [27].

This entry provides an overview of CAT. Some suggested further readings on CAT include [25], [23], [9]; [7], and [13].

The Basic CAT Algorithm

A CAT algorithm is an iterative process designed to tailor an examination to an individual examinee's ability. CAT employs an item database that typically contains three types of information about each item: (a) the item text and other rendering data that is used by the testing software to present the item to the test taker and capture his or her response; (b) the answer key; and (c) **item response theory** (IRT) item parameter estimates. The IRT item parameter estimates are frequently based on the one-, two-, or three-parameter IRT model (e.g., see [7] and [9]) and must be calibrated to common scale. For example, if the three-parameter model is used, the item database will contain a discrimination parameter estimate, a_i , a difficulty parameter estimate, b_i , and a pseudo-guessing parameter, c_i , for $i = 1, \dots, I$ items in

the database. The database may also contain item exposure control parameters that are used to restrict the overexposure of the best items, as well as various content and other coded item attributes that may be used by the CAT item selection algorithm.

CAT also requires test delivery software – sometimes called the *test driver* – that provides three basic functions. First, the software must render each item on-screen and store the test taker's response(s). Second, the software must be capable of computing provisional IRT proficiency scores for the examinees. These can be **maximum likelihood** scores, Bayes mean scores, or Bayes modal scores (see, for example, references [12] and [21]). IRT scores are computed using the examinee's responses to a series of items and the associated IRT item parameter estimates. For example, the Bayes modal scores [12] can be expressed as

$$\hat{\theta}_{u_{i_1} \dots u_{i_{k-1}}}^{MAP} \equiv \max_{\theta} \{g(\theta|u_{i_1}, \dots, u_{i_{k-1}}) : \theta \in (-\infty, \infty)\} \quad (1)$$

where the value of θ at maximum of the posterior likelihood function, $g(\theta|u_{i_1}, \dots, u_{i_{k-1}})$, is the model estimate of θ . Finally, the software must select the remaining items for each examinee using an adaptive algorithm to maximize the IRT item information at the provisional ability estimate, $\hat{\theta}_{u_{i_1} \dots u_{i_{k-1}}}$. That is, given the unselected items in an item database, R_k , an item is selected to satisfy the function

$$i_k \equiv \max_j \{I_{U_j}(\hat{\theta}_{u_{i_1}, \dots, u_{i_{k-1}}}) : j \in R_k\}. \quad (2)$$

This item selection mechanism is described in more depth in the next section.

A CAT actually begins with a brief 'burn-in' period that usually involves the administration of a very small random sample of items. This sample of items is meant to provide a reasonable starting estimate of the examinee's ability, prior to activating the adaptive algorithm. Following the burn-in period, CAT resolves to an iterative three-step process, cycling through the above three functions. That is, the test delivery software: (a) selects the next item to maximize information at the provisional score; (b) renders the item and captures the examinee's response(s); and (c) updates the provisional score and returns to Step 1. As more items are administered, the CAT software is able to incrementally improve the accuracy of the provisional score for the examinee. The CAT terminates when a stopping rule has been

Figure 1 The iterative CAT process

satisfied. Two standard stopping rules for adaptive tests are: (a) a fixed test length has been met or (b) a minimum level of score precision has been satisfied¹. This iterative process of selecting and administering items, scoring, and then selecting more items is depicted in Figure 1.

In Figure 1, the initial items are usually transmitted through a computer network and rendered at the examinee's workstation. The responses are captured and scored by the test delivery software. The scored response vector and the item parameters are then used to update the provisional estimate of θ . That provisional score is

then used by maximum information algorithm, $i_k \equiv \max_j \{ I_{U_j}(\hat{\theta}_{u_1, \dots, u_{i_{k-1}}}) : j \in R_k \}$, to select the next item. The test terminates when either a fixed number of items have been administered or when a particular statistical criterion has been attained.

It is important to realize that each item incrementally improves our statistical confidence about an examinee's unknown proficiency, θ . For example, Figure 2 shows the degree of certainty about an examinee's score after 3 items and again after 50 items. For the sake of this example, assume that we know that this examinee's *true proficiency score* to be $\theta = 1.75$. After administering only 3

Figure 2 Certainty about proficiency after three and after fifty items

items, our certainty is represented by dotted curve is relatively flat indicating a lack of confidence about the exact location of the *provisional* estimate. However, after administering 50 items, we find that: (a) the *provisional* score estimate is quite close to the *true proficiency*; and (b) our certainty is very high, as indicated by the tall, narrow curve.

IRT Information and Efficiency in CAT

To better understand how the adaptive algorithm actually works, we need to focus on the IRT item and test information functions. Birnbaum [1] introduced the concept of the test information function as a psychometric analysis mechanism for designing and comparing the measurement precision of tests in the context of item response theory (IRT). Under IRT, the conditional measurement error variance, $\text{var}(E|\theta)$, is inversely proportional to the test information function, $I(\theta)$. That is,

$$\text{var}(E|\theta) = [I(\theta)]^{-1} = \frac{1}{\sum_{i=1}^n I_i(\theta)} \quad (3)$$

Figure 3 Proficiency scores and standard errors for a 50-item CAT for two hypothetical examinees

where $I_i(\theta)$ is the item information function at some proficiency score of interest, denoted as θ . The exact mathematical form of the information function varies by IRT model. Lord [9] and Hambleton and Swaminathan [7] provide convenient computational formulas for the one-, two-, and three-parameter IRT model information functions.

Equation (3) suggests two important aspects about measurement precision. First, each item contributes some amount of measurement information to the reliability or score precision of the total test. That is, the total test information function is sum of the item information functions. Second, by increasing the test information function, we correspondingly reduce the measurement error variance of the estimated θ score. Simply put, when test information is maximized, measurement errors are minimized.

Figure 3 shows what happens to the provisional proficiency scores and associated standard errors (the square root of the error variance from (3)) for two hypothetical examinees taking a 50-item CAT. The proficiency scale is shown on the vertical axis (-1.5 to $+1.5$). The sequence of 50 adaptively administered items is shown on the horizontal scale. Although not shown in the picture, initially, both examinees start with proficiency estimates near zero. After the first item is given, the estimated proficiency

scores immediately begin to separate ($\blacktriangle$ for Examinee A and $\blacktriangledown$ for Examinee B). Over the course of 50 items, the individual proficiency scores for these two examinees systematically diverge to their approximate true values of +1.0 for Examinee A and -1.0 for Examinee B. The difficulties of the 50 items selected for each examinee CAT would track in a pattern similar to the symbols plotted for the provisional proficiency scores. The plot also indicates the estimation errors present throughout the CAT. The size of each error band about the proficiency score denotes the relative amount of error associated with the scores. Larger bands indicate more error than narrower bands. Near to the left side of the plot the error bands are quite large, indicating fairly imprecise scores. During the first half of the CAT, the error bands rapidly shrink in size. After 20 items or so, the error bands tend to stabilize (i.e., still shrink, but more slowly). This example demonstrates how the CAT quickly reduces error variance and improves the efficiency of a test.

In practice, we can achieve maximum test information in two ways. We can choose highly discriminating items that provide maximum item information within particular regions of the proficiency scale or at specific proficiency scores – that is, we sequentially select items to satisfy (2). Or, we can merely continue adding items to increment the amount of information until a desired level of precision is achieved. Maximizing the test information at each examinee's score is tantamount to choosing a customized, optimally reliable test for each examinee.

A CAT achieves either improvements in relative efficiency or a reduction in test length. Relative efficiency refers to a proportional improvement in test information and can be computed as the ratio of test information functions or reciprocal error variances for two tests (see (3); also see [9]). This relative efficiency metric can be applied to improvements in the accuracy of proficiency scores or to decision accuracy in the context of mastery tests or certification/licensure tests. For example, if the average test information function for a fixed-item test is 10.0 and the average test information function for an adaptive test is 15.0, the adaptive test is said to be 150% as efficient as the fixed-item test. Measurement efficiency is also associated with reductions in test length. For example, if a 20-item adaptive test can provide the same precision as a 40-item nonadaptive test, there is an obvious reduction the amount of test materials

needed and less testing time needed (assuming, of course, that a shorter test ought to take substantially less time than a longer test). Much of the early adaptive testing research reported that typical fixed-length academic achievement tests used could be reduced by half by moving to a computerized adaptive test² [25]. However, that early research ignored the perceptions by some test users – especially in high-stakes testing circles – that short adaptive tests containing only 10 or 20 items could not adequately cover enough content to make valid decisions or uses of scores. Today, CAT designs typically avoid such criticism by using either fixed lengths or at least some minimum test length to ensure basic content coverage.

Nonetheless, CAT does offer improved testing efficiency, which means we can obtain more confident estimates of examinees' performance using fewer items than are typically required on nonadaptive tests. Figure 4 shows an example of the efficiency gains for a hypothetical CAT, compared to a test for which the items were randomly selected. The item characteristics used to generate the test results for Figure 4 are rather typical of most professionally developed achievement tests. The plot shows the *average* standard errors – the square root of the error variance from (3) – over the sequence of 50 items (horizontal axis). The standard errors are averaged for a sizable sample of examinees having different proficiency scores.

In Figure 4, we can more specifically see how the errors decrease over the course of the two tests. It is important to realize that the errors decrease for a randomly selected set of items, too. However, CAT clearly does a better job of more rapidly reducing the errors. For example, at 20 items, the CAT achieves nearly the same efficiency as the 50-item random test; at 50 items, the average standard error for the CAT is approximately half as large as for the random test.

Security Risks in CAT

The risks to the security of computer-based tests are somewhat analogous to the cheating threats faced by gambling casinos or lotteries. Given any type of high stakes (e.g., entrance into graduate school, scholarships, a coveted course placement, a job, a license, a professional certificate), there will be some group of cheaters intent on *beating-the-odds* (of random chance or luck) by employing well

Figure 4 Average standard errors for a 50-item CAT versus 50 randomly selected items

thought out strategies, which provide them with any possible advantage, however slight that may be. One of the most common security risks in high-stakes CAT involves groups of examinees collaborating to memorize and share items, especially when the same item database is active over a long period of time, and testing is nearly continuous during that time period.

Unfortunately, the CAT algorithm actually exacerbates the security risks associated with cheating through systematic memorization of an item database. That is, because the CAT algorithm chooses the items to be maximally informative for each examinee, the most discriminating items are chosen far more often than the less discriminating items. This means that the *effective* item pool will typically be quite small since only a subset of the entire item database is being used. Beyond the bad economic policy of underutilizing an expensive commodity such as a large portion of an item database, cheaters gain the advantage of only needing to memorize and share the most highly exposed items.

Three of the methods for dealing with over-exposure risks in high-stakes CAT are: (a) increasing the size of the active item database; (b) rotating item databases over time (intact or partially); and (c) specifically controlling item exposures as part of the computerized test assembly process. The latter approach involves a modification to the CAT

item selection algorithm. Traditional exposure control modifications cited in the psychometric literature include maximum information item selection with the Simpson–Hetter unconditional item exposure control procedure (see references [8] and [20]), maximum information and Stocking and Lewis (conditional) item exposure control procedure (see [17, 18] and [19]), and maximum information and stochastic (conditional) exposure control procedure (see [14], [15]). An extensive discussion of exposure controls is beyond the scope of this entry.

CAT Variations

In recent years, CAT research has moved beyond the basic algorithm presented earlier in an attempt to generate better strategies for controlling test form quality control and simultaneously reducing exposure risks. Some testing programs are even moving away from the idea of an item as the optimal unit for CAT. Four promising CAT variations are: (a) constrained CAT using shadow tests (CCAT-UST); (b) α -Stratified Computerized Adaptive Testing (AS-CAT); (c) testlet-based CAT (T-CAT); and computer-adaptive multistage testing (CA-MST). These four approaches are summarized briefly, below.

Van der Linden and Reese [24] introduced the concept of a *shadow test* as a method of achieving an optimal CAT in the face of numerous content and other test assembly constraints (also see van der Linden [22]). Under CCAT-UST, a complete test is reassembled following each item administration. This test, called the *shadow test*, incorporates all of the required content constraints, item exposure rules, and other constraints (e.g., cognitive levels, total word counts, test timing requirements, clueing across items), and uses maximization of test information at the examinee's current proficiency estimate as its objective function. The shadow test model is an efficient means for balancing the goals of meeting content constraints and maximizing test information.

A shadow test actually is a special case of content-constrained CAT that explicitly uses automated test assembly (ATA) algorithms for each adaptive item selection. In that regard, this model blends the efficiency of CAT with the sophistication of using powerful linear programming techniques (or other ATA heuristics) to ensure a psychometrically optimal test that simultaneously meets any number of test-level specifications and item attribute constraints. Shadow testing can further incorporate exposure control mechanisms as a security measure to combat some types of cheating [22].

a-Stratified computerized adaptive testing (AS-CAT; [4]) is an interesting modification on the adaptive theme. AS-CAT adapts the test to the examinee's proficiency – like a traditional CAT. However, the AS-CAT model eliminates the need for formal exposure controls and makes use of a greater proportion of the test bank than traditional CAT. As noted earlier, the issue of test bank use is extremely important from an economic perspective (see the section Security Risks in CAT). *a*-Stratified CAT partitions the test bank into ordered layers, based on statistical characteristics of the items (see [4], [3]). First, the items are sorted according to their estimated IRT item discrimination parameters³. Second, the sorted list is partitioned into layers (the strata) of a fixed size. Third, one or more items are selected within each strata by the usual CAT maximum information algorithm. AS-CAT then proceeds sequentially through the strata, from the least to the most discriminating strata. The item selections may or may not be subject to also meeting applicable content specifications or constraints. Chang and Ying reasoned that,

during the initial portion of an adaptive test, less discriminating items could be used since the proficiency estimates have not yet stabilized. This stratification strategy effectively ensures that most discriminating items are saved until later in the test when they can be more accurately targeted to the provisional proficiency scores. In short, the AS-CAT approach avoids wasting the 'high demand' items too early on in the test and makes effective use of the low demand items that, ordinarily, are seldom if ever selected in CAT. Chang, Qian, and Ying [2] went a step further to also block the items based on the IRT difficulty parameters. This modification is intended to deal more effectively with exposure risks when the IRT discrimination and difficulty parameters are correlated with each other within a particular item pool.

One of the principal complaints from examinees about CAT is the inability for them to skip items, or review and change their answers to previously seen items. That is, because the particular sequence of item selections in CAT is dependent on the provisional scores, item review is usually prohibited. To address this shortcoming in CAT, Wainer and Kiely [26] introduced the concept of a *testlet* to describe a subset of items or a 'mini-test' that could be used in an adaptive testing environment. A testlet-based CAT (TB-CAT) involves the adaptive administration of preassembled *sets* of items to an examinee, rather than single items. Examples of testlets include sets of items that are associated with a common reading passage or visual stimulus, or a carefully constructed subset of items that mirrors the overall content specifications for a test. After completing the testlet, the computer scores the items within it and then chooses the next testlet to be administered. Thus, this type of test is adaptive at the testlet level rather than at the item level. This approach allows examinees to skip, review, and change answers within a block of test items. It also allows for content and measurement review of these sets of items prior to operational administration.

It should be clear that testlet-based CATs are only partially adaptive since items within a testlet are administered in a linear fashion. However, TB-CAT offers a compromise between the traditional, nonadaptive format and the purely adaptive model. Advantages of TB-CAT include increased testing efficiency relative to nonadaptive tests; the ability of content experts and sensitivity reviewers to review individual, preconstructed testlets and subtests to

evaluate content quality; and the ability of examinees to skip, review, and change answers to questions within a testlet.

Similar in concept to TB-CAT is computer-adaptive multistage testing (CA-MST). Luecht and Nungester [11] introduced CA-MST under the heading of ‘computer-adaptive sequential testing’ as a framework for managing real-life test construction requirements for large-scale CBT applications (also see [10]). Functionally, CA-MST is a preconstructed, self-administering, multistage adaptive test model that employs testlets as the unit of selection. The primary difference between TB-CAT and CA-MST is that the latter prepackages the testlets, scoring tables, and routing rules for the test delivery software. It is even possible to use number-correct scoring during the real-time administration, eliminating the need for the test delivery software to have to compute IRT-based scoring or select testlets based on a maximum information criterion.

Like TB-CAT, CA-MST uses preconstructed testlets as the fundamental building blocks for test construction and test delivery. Testlets may range in size from several items to well over 100 items. The testlets are usually targeted to have specific statistical properties (e.g., a particular average item difficulty or to match a prescribed IRT information function) and all content balancing is built into the construction of the testlets. As part of the ATA process, the preconstructed testlets will be further prepackaged in small collections called ‘panels’. Each panel contains four to seven (or more) testlets, depending on the panel design chosen – an issue addressed below. Each testlet is explicitly assigned to a particular stage and to a specific route within the panel (easier, moderate, or harder) based upon the average difficulty of the testlet. Multiple panels can be prepared with item overlap precisely controlled across different panels.

CA-MST is adaptive in nature and is therefore more efficient than using fixed test forms. Yet, CA-MST provides explicit control over content validity, test form quality, and the exposure of test materials.

Notes

1. For pass/fail mastery tests that are typically used in certification and licensure testing, a different stopping rule can be implemented related to the desired statistical confidence in the accuracy of the classification decision(s).

2. Although adaptation is clearly important as a psychometric criterion, it is easy sometimes to overstate the real cost-reduction benefits that can be specifically attributed to gains in measurement efficiency. For example, measurement efficiency gains from adaptive testing are often equated with reduced testing time. However, any potential savings in testing time may prove to be unimportant if a computer-based examination is administered at commercial CBT centers. That is, commercial CBT centers typically charge fixed hourly rates per examinee and require a guaranteed [minimum] testing time. Therefore, if the CBT test center vendor negotiates with the test developer for a four-hour test, the same fee may be charged whether the examinee is at the center for two, three, or four hours.
3. See [7] or [9] for a more detailed description of IRT item parameters for multiple-choice questions and related objective response items.

Computer-based Test Designs

Across disciplines and contexts, more and more tests are being implemented as computerized assessments, with examinees viewing and responding to test questions via a desktop PC and, in some cases, also via the Internet. This transition in the administration mode is happening the world over, and many of the benefits of computerization are well documented in the growing computer-based testing (CBT) literature (see edited books by Van der Linden and Glas [20] and Mills et al. [14] for excellent overviews of the state of the art). Briefly, some of the measurement advantages to be realized in operational CBT concern how a computer-based test is implemented [3], and some possible sources of variation include the choice of item type, scoring method, the relative inclusion of multimedia and other technological innovations in the test administration, the procedures for item and item bank development, and test designs. This last issue of test designs, sometimes discussed as test models, refers to structural variations in test administration and how a computerized test will be implemented with respect to whether the specific items presented to an examinee are selected and grouped beforehand or are chosen during the test administration (*see Test Construction: Automated*).

Whereas paper-based tests are by and large static and form-based for very sensible logistical reasons, in computer-based testing (CBT), test developers have the power and memory of the computer at their disposal to be more or less variable during the course of the actual test administration. Such flexibility has helped to make the topic of test designs a significant area for research among test developers, particularly given the clear evidence in the psychometric literature for improved measurement under adaptive test designs in CBT [4].

The possibilities that (a) tests need not be exactly identical in sequence or test length and that (b) alternative designs could be implemented can be traced back to early work on intelligence testing, which was carried out very early in the twentieth century [1]. In these pioneering paper-based tests, both starting and termination points varied across students and were dependent on the responses provided by individual examinees. From that work and later studies by many

researchers including Lord [9, 10], the notion of tailoring tests to individual examinees was further developed, and today the continuum of test designs used in practice with CBT ranges from linear fixed-form tests assembled well in advance of the test administration to tests that are adaptive by item or by sets of items to be targeted at the estimated ability of each examinee individually. Each of these designs possess a variety of benefits and drawbacks for different testing constructs, and making the choice among such designs involves considerable thought and research on the part of a credentialing testing organization about the nature of the construct, the level of measurement precision necessary, and the examinee population.

It is generally established in the measurement literature that there are three families of available test designs for CBT. One of these is not adaptive (the linear fixed-form test design) and the other two are adaptive (multistage test designs and computer-adaptive test designs). Thus, a primary distinction among test designs that can be made concerns the property of being adaptive or not, and the further distinction is whether the test is adaptive at the item level or between sets of items. Traditionally, linear forms have predominated operational testing (both paper-and-pencil and computer-based). However, the advances in research into item response theory (IRT) (*see Item Response Theory (IRT) Models for Polytomous Response Data; Item Response Theory (IRT) Models for Rating Scale Data*) over the years [7, 8, 12] as well as the advent of powerful and inexpensive desktop computers have facilitated implementation of adaptive test models. Such methods are described as adaptive in the sense that the sequence of items or sets of items administered to an individual examinee is dependent on the previous responses provided by the examinee [11].

Computerized Fixed Tests

The first test design, the nonadaptive linear fixed-form test, has been widely implemented in both paper-and-pencil tests and CBTs. In a CBT context, the linear fixed-form test is sometimes referred to as a computerized fixed test, or CFT [16]. CFT involves the case where a fixed set of items is selected to comprise a test form, and multiple parallel test forms may be created to maintain test security and to ensure ample usage of the item bank. In this approach, test

2 Computer-based Test Designs

forms may be constructed well in advance of actual test administration or assembled as the examinee is taking the test. This latter circumstance, commonly referred to as linear-on-the-fly testing, or LOFT, is a special case of CFT that uses item selection algorithms, which do not base item selection on estimated examinee ability; rather, selection of items proceeds relative to other predefined content and other statistical targets [2]. Each examinee receives a unique test form under the LOFT design, but this provides benefits in terms of item security rather than psychometric efficiency [4]. Making parallel forms or introducing some randomization of items across forms are additional methods by which test developers address item exposure and test security concerns in CFT.

Patelis [17] identified some other advantages associated with CFT including (a) the opportunity for examinees to review, revise, and omit items, and (b) the perception that such tests are easier to explain to examinees. At the same time, there are some disadvantages to linear test forms, and these are similar to those arising with paper-based tests. With static forms, each form may be constructed to reflect a range of item difficulty in order to accurately assess examinees of different abilities. Consequently, the scores for some examinees (and especially those at the higher and lower ability levels) may not be as precise as it would be in a targeted test.

The linear test designs possess many benefits for measurement, and depending on the purpose of testing and the degree of measurement precision needed they may be wholly appropriate for many large-scale testing organizations. However, other agencies may be more interested in other test designs that afford them different advantages, such as the use of shorter tests and the capacity to obtain more precise measurement all along the ability distribution and particularly near the cut-score where pass-fail decisions are made in order to classify examinees as masters or nonmasters. The remaining two families of test designs are considered to be adaptive in nature, though they do differ somewhat with respect to structure and format.

Multistage Tests

The second family of test designs, multistage testing (MST), is often viewed as an intermediary step between a linear test and a computer-adaptive test (CAT). As a middle ground, MST combines the

adaptive features of CAT with the opportunity to preassemble portions of tests prior to administration as is done with linear testing [6]. MST designs are generally defined by using multiple sets of items that vary on the basis of difficulty and routing examinees through a sequence of such sets on the basis of the performance on previous sets. With sets varying by difficulty, the particular sequence of item sets that any one examinee is presented with as the test is administered is chosen based on an examinee's estimated ability, and so the test 'form' is likely to differ for examinees of different ability levels. After an examinee finishes each item set, that ability estimate is updated to reflect the new measurement information obtained about that examinee's ability through administration of the item set. In MST terminology, these sets of items have come to be described as *modules* [13] or *testlets* [21], and can be characterized as short versions of linear test forms, where some specified number of individual items are administered together to meet particular test specifications and provide a certain proportion of the total test information. The individual items in a module may be all related to one or more common stems (such as passages or graphics) or be more generally discrete from one another, per the content specifications of the testing program for the test in question. These self-contained, carefully constructed, fixed sets of items are the same for every examinee to whom each set is administered, but any two examinees may or may not be presented with the same sequence of modules. Most of the common MST designs use two or three stages. However, the actual number of stages that could be implemented could be set higher (or lower) given the needs of different testing programs.

As a test design, MST possesses a number of desirable characteristics. Examinees may change answers or skip test items and return to them, prior to actually finishing a module and moving on to another. Of course, after completing a stage in MST, however, the items within that stage are usually scored using an appropriate IRT model and the next stage is selected adaptively, so no return to previous stages can be allowed (though, again, item review within a module at each stage is permissible). Measurement precision may be gained over CFT or LOFT designs without an increase in test length by adapting the exam administration to the performance levels of the examinees [11, 18]. If optimal precision of individual

proficiency estimates is desired, however, empirical studies have similarly demonstrated that scores obtained from MST are not quite as statistically accurate as those from CAT [18].

Computerized-adaptive Tests

In some ways, the third family of test designs, CAT, can be viewed as a special case of the MST model to the extent that CAT can be thought of as an MST made up of n stages with just one item per stage. In both cases, the fundamental principle is to target test administration to the estimated ability of the individual. There are differences, of course: as item selection in CAT is directly dependent on the responses an examinee provides to each item singly, no partial assembly of test forms or stages takes place for a computerized-adaptive test prior to test administration. Furthermore, given that CAT is adaptive at the item level, Lord [11] and Green [5] indicate that this test design provides the most optimal estimation of examinee proficiency all along the ability continuum relative to other test designs. Indeed, CAT has been widely implemented in a variety of testing contexts where precision all along the ability scale is desired, such as admissions testing.

In CAT, if an examinee early on in a test exhibits high ability, that person need not be presented with many items of low difficulty, and conversely, a low-ability examinee would not receive many very hard items. With such efficiency, test length may also be reduced. Other advantages associated with adaptive testing include enhanced test security, testing on demand, individualized pacing of test administration, immediate scoring and reporting of results, and easier maintenance of the item bank [8].

At the same time, CAT is administratively more complex, involves a changed approach to test development and score reporting, which is something of a departure from the procedures used in paper-and-pencil testing, and presents its own security concerns per [15]. Also, an oft-cited shortcoming of CAT from the perspective of examinees is the issue of item review as discussed by [19]. Whereas in traditional paper-based administration, examinees can go back and change answers as they see fit, this is not an option in most implementations of CAT because of the nature of the adaptive algorithm.

Conclusions

The computerization of assessment has facilitated immense flexibility, and the families of designs presented here characterize the range of available options. Each type of test design clearly presents certain benefits for different testing contexts, and the measurement advantages associated with the choice of design for any one situation must be weighed against operational realities. By knowing the alternatives and the properties of each, test developers can use this information to produce tests that are both maximally informative and psychometrically sound given the purpose for testing and the kinds of decisions to be made on the basis of test scores.

Computer-based Testing

As most broadly defined, computer-based tests (CBTs) include not just tests administered on computers or workstations but also exams delivered via telephones, PDAs, and other electronic devices [1]. There have been three main reasons for test developers to move beyond conventional paper-and-pencil administration. The first is to change the nature of what is being measured [2, 10]. The second is to improve measurement precision or efficiency [18, 19]. The third is to make test administration more convenient for examinees, test sponsors, or both.

Changed Measurement

Standardized tests are often criticized as artificial and abstract, measuring performance in ways divorced from real-world behaviors [5]. At least some of this criticism is due to the constraints that paper-based administration imposes upon test developers. Paper is restricted to displaying static text and graphics, offers no real means of interacting with the examinee, and sharply limits the ways in which examinees can respond. Computers can free test developers from these restrictions. They can present sound and motion, interact dynamically with examinees, and accept responses through a variety of modes. For example,

- A CBT assessing language proficiency can measure not just how well an examinee can read and write but also their ability to comprehend spoken language, speak, and even converse [14].
- A CBT measuring proficiency with a software package can allow examinees to interact directly with that software to determine or even generate their responses.
- A selection test for prospective air traffic controllers can allow examinees to interact with and control simulated air traffic in a realistic environment [12].
- A science test can allow students to design and conduct simulated experiments as a means of responding.
- A medical certification exam can allow examinees to interactively evaluate, diagnose, treat, and manage simulated patients [3].

As these examples illustrate, a CBT can be a richer, more realistic experience that allows more direct measurement of the traits in question.

Improved Measurement Precision and Efficiency

An important type of CBT is termed *adaptive* because of the test's ability to tailor itself to uniquely suit an examinee's level of performance. As an *adaptive test* proceeds, answers to earlier questions determine which questions are asked later. The test, therefore, successively changes as the examinee's performance level is revealed [11, 18, 19].

At least three types of adaptive tests can be distinguished, but all consist of two basic steps: item selection and score estimation. Both are repeated each time an item (or set of items) is presented and answered. The first step determines the most appropriate item or set of items to administer given what is currently known about the examinee's performance level. Items or sets are selected from a *pool* containing many more items than any single examinee sees. Sets may comprise either items that share some natural connection to each other or items that are more arbitrarily linked. An example of the former is a reading passage to which several items are attached.

The second step uses the response or responses to the item or items previously presented to refine the score or performance estimate so that the next item or set presented can be more appropriate still. This cycle continues until either a specified number of items have been administered or some measure of score precision is reached. The process is represented schematically by Figure 1.

All of the adaptive testing strategies select items and assemble tests to best meet some or all of three

Figure 1 The adaptive testing process

goals, which usually conflict with one another [11]. The first is to maximize test efficiency by measuring examinees to appropriate levels of precision with as few items as possible. The competing adaptive testing strategies have evolved largely because different definitions can be attached to terms like ‘efficiency,’ ‘appropriate,’ and ‘precision.’ In any case, achieving this goal can allow an adaptive test to match or better the precision of a conventional test that is several times longer.

The second goal is that each examinee’s test be properly balanced in terms of item substance or content. This is important to ensure that tests are content valid and meet both examinees’ and score users’ subjective expectations of what a proper test should measure. The intent is to force adaptive tests to meet proper test-construction standards despite their being assembled ‘on-the-fly’ as the test proceeds [15].

A third goal is to control or balance the rates at which various items in the pool are administered [16]. The concern is that without such control, a small number of items might be administered very frequently while others rarely or never appear.

The potential conflicts between these goals are many. For example, imposing strict content standards is likely to lower test precision by forcing the selection of items with less optimal measurement properties. Protecting the administration rates of items with exceptional measurement properties will have a similar effect on precision. Every adaptive test must therefore strike a balance between these goals. The three basic testing strategies that will be described do so in fundamentally different ways.

CATs and MSTs

The first two types of adaptive tests to be described share a common definition of test precision. Both the *computerized adaptive test* (CAT) and the *multi-stage test* (MST) attempt to accurately and efficiently estimate each examinee’s location on a continuous performance or score scale. This goal will be distinguished below from that of *computerized classification tests*, which attempt to accurately assign each examinee to one of a small number of performance strata. Where CATs and MSTs differ is in the way this goal of maximum precision is balanced with the competing interests of controlling test content and the rates at which various items are administered.

In essence, the two strategies differ in the way and the extent to which the testing process is permitted to adapt.

The CAT selects items from the pool individually or in small sets. A wide range of item selection criteria have been proposed. Some of these operate from different definitions of precision; others try to recognize the difficulty inherent in making optimal decisions when information about examinee performance is incomplete and possibly misleading. Still others more explicitly subordinate measurement precision to the goals of balancing content and item exposure.

Test scoring methods also vary widely, although nearly all are based on **item response theory** (IRT) [8]. These procedures assume that all items in the pool are properly characterized and lie along a single IRT proficiency scale. A test score is then an estimate of the examinee’s standing on this same scale. **Maximum likelihood** and Bayesian estimation methods (see **Bayesian Item Response Theory Estimation**) are most commonly used. However, a number of more exotic estimation procedures have been proposed, largely with the goal of increased statistical robustness [17].

Because of the flexibility inherent in the process, the way in which a CAT unfolds is very difficult to predict. If the item pool is reasonably large (and most researchers recommend the pool contain at least 8–10 times more items than the test length), the particular combination of items administered to any examinee is virtually unique [9]. This variation has at least three sources. First, different items are most appropriate for different examinees along the proficiency scale. In general, easy items are most appropriate for low-scoring examinees while harder items are reserved for more proficient examinees. Second, each response an examinee makes can cause the test to move in a new direction. Correct answers generally lead to harder questions being subsequently selected while wrong answers lead to easier questions in the future. Finally, most item selection procedures incorporate a random element of some sort. This means that even examinees of similar proficiency who respond in similar ways are likely to see very different tests.

Although the changing and unpredictable nature of the CAT is the very essence of test adaptation, it can also be problematic. Some item selection procedures can ‘paint themselves into a corner’ and have no choice but to administer a test that fails to conform to all test-construction rules. Measurement precision

and overall test quality can also differ widely across examinees. Because tests are assembled in real time and uniquely for each examinee, there is obviously no opportunity for forms to be reviewed prior to administration. All of these concerns contributed to the development of multistage testing.

The MST is a very constrained version of CAT, with these constraints being imposed to make the testing process more systematic and predictable [7]. Development of an MST begins by assembling all of the available pool items into a relative handful of short tests, often called *testlets*, some of which target specific proficiency levels or ranges [20]. Content and item exposure rate considerations can be taken into account when assembling each testlet. A common practice is to assemble each testlet as a miniature version of an entire form.

Test administration usually begins by presenting each examinee with a testlet that measures across a wide proficiency range. The testlet is presented intact, with no further selection decision made until the examinee has completed all of its items. Once the initial testlet is completed, performance is evaluated and a selection decision is made. Examinees who performed well are assigned a second testlet that has been assembled to best measure higher proficiency ranges. Examinees who struggled are assigned a testlet largely comprising easier items. The logic inherent in these decisions is the same as that employed by the CAT, but selection decisions are made less frequently and the range of options for each decision is sharply reduced (since there are usually far fewer testlets available than there are items in a CAT pool). Scoring and routing decisions can be made based either on IRT methods similar to those used in CAT, or on conventional number-right scores. The former offers theoretical and psychometric advantages; the latter is far simpler operationally.

MSTs differ in the number of levels (or choice points) that each examinee is routed through. The number of proficiency-specific testlets available for selection at each level also differs. In simpler, more restrictive cases – those involving fewer levels and fewer testlets per level – it is quite possible to construct and review all of the test forms that could possibly be administered as combinations of the available elements. In all cases, the particular form administered via an MST is far more predictable than the outcome of a CAT. The price paid for increased predictability is a loss of flexibility and a decrease in

test efficiency or precision. However, this decrease can be relatively minor in some cases.

Computerized Classification Tests

Also called a *computerized mastery test*, the *computerized classification test* (CCT) is based on a very different premise [6, 13]. Rather than trying to position each examinee accurately on a proficiency scale, the CCT instead tries to accurately sort examinees into broad categories. The simplest example is a test that assigns each examinee to either of two classes. These classes may be labeled master versus nonmaster, pass versus fail or certified versus not certified. Classification is based around one or more *decision thresholds* positioned along the proficiency scale.

The CCT is an attractive alternative for the many testing applications that require only a broad grouping of examinees. Because it is far easier to determine whether an examinee is above or below a threshold than it is to position that examinee precisely along the continuous scale, a CCT can be even shorter and more efficient than a CAT. CCTs also lend themselves naturally to being of variable length across examinees. Examinees whose proficiency lies well above or below a decision threshold can be reliably classified with far fewer items than required by examinees who lie near that threshold.

CCTs are best conducted using either of three item selection and examinee classification methods. The first makes use of *latent class* IRT models, which assume a categorical rather than continuous underlying proficiency scale [4]. These models naturally score examinees through assignments to one of the latent classes or categories.

A second approach uses the *sequential probability ratio test* (SPRT), which conducts a series of likelihood ratio tests that lead ultimately to a classification decision [13]. The SPRT is ideally suited to tests that vary in length across examinees. Each time an item is administered and responded to, the procedure conducts a statistical test that can have either of two outcomes. The first is to conclude that an examinee can be classified with a stated level of confidence given the data collected so far. The second possible outcome is that classification cannot yet be confidently made and that testing will need to continue. The test ends either when a classification is made with confidence or some maximum number of items

4 Computer-based Testing

have been administered. In the latter case, the decision made at the end of the test may not reach the desired level of confidence. Although IRT is not necessary to administering a test under the SPRT, it can greatly increase test precision or efficiency.

The third strategy for test administration and scoring uses Bayesian decision theory to classify examinees [6]. Like the SPRT, Bayes methods offer control over classification precision in a variable length test. Testing can therefore continue until a desired level of confidence is reached. Bayes methods have an advantage over the SPRT in being more easily generalized to classification into more than two categories. They are also well supported by a rich framework of statistical theory.

Item selection under classification testing can be very different from that under CAT. It is best to select items that measure best at the classification thresholds rather than target examinee proficiency. Naturally, it is much easier to target a stationary threshold than it is to hit a constantly changing proficiency estimate. This is one factor in CCT's improved efficiency over CAT. However, the primary factor is that the CCT does not distinguish between examinees who are assigned the same classification. They are instead considered as having performed equally. In contrast, the CAT is burdened with making such distinctions, however small. The purpose of the test must, therefore, be considered when deciding whether the CAT or the CCT is the most appropriate strategy.

Operational Convenience

The third benefit of computerized testing is operational convenience for both examinees and test sponsors. These conveniences include:

Self-proctoring

Standardized paper and pencil tests often require a human proctor to distribute test booklets and answer sheets, keep track of time limits, and collect materials after the test ends. Administering a CBT can be as simple as parking an examinee in front of a computer. The computer can collect demographic data, orient the examinee to the testing process, administer and time the test, and produce a score report at the conclusion. Different examinees can sit side by side taking different tests with different time limits for

different purposes. With conventional administration, these two examinees would likely need to be tested at different times or in different places.

Mass Customization

A CBT can flexibly customize itself uniquely to each examinee. This can go well beyond the sort of adaptivity discussed above. For example, a CBT can choose and administer each examinee only the appropriate components of a large battery of tests. Another example would be a CBT that extended the testing of failing examinees in order to provide detailed diagnostic feedback useful for improving subsequent performance. A CBT also could select or adjust items based on examinee characteristics. For example, spelling and weight and measurement conventions can be easily matched to the location of the examinee.

Reach and Speed

Although a CBT can be administered in a site dedicated to test administration, it can also be delivered anywhere and anytime a computer is available. Examinees can test individually at home over the Internet or in large groups at a centralized testing site.

It is also possible to develop and distribute a CBT much faster than a paper test can be formatted, printed, boxed and shipped. This can allow tests to change rapidly in order to keep up with fast-changing curricula or subject matter.

Flexible Scheduling

Many CBT testing programs allow examinees to test when they choose rather than requiring them to select one of several periodic mass administrations. Allowing examinees to schedule their own test date can be more than just a convenience or an invitation to procrastinate. It can also provide real benefits and efficiencies. For example, examinees in a training program can move directly to certification and employment without waiting for some distant test administration date to arrive.

Immediate Scoring

Many CBTs are able to provide examinees with a score report immediately upon conclusion of the test.

This is particularly important when coupled with flexible scheduling. This can allow examinees to meet tight application deadlines, move directly to employment, or simply decide that their performance was substandard and register to retest.

Summary

Any description of computer-based testing is almost certain to be out-of-date before it appears in print. Things are changing quickly and will continue to do so. Over the last two decades, CBT has evolved from a largely experimental procedure under investigation to an operational procedure employed by hundreds of testing programs serving millions of examinees each year [2]. Even faster growth can be expected in the future as technology becomes a more permanent fixture of everyone's lives. Testing on computer may eventually become an even more natural behavior than testing on paper has ever been.

Concordance Rates

In genetic studies of medical conditions, the degree of similarity between twins is often calculated using concordance rates. These concordance rates are useful to study the relative importance of genes and environment. Monozygotic (MZ) twins share all of their genes, whereas dizygotic (DZ) twins share on an average half of their genes. Therefore, a higher concordance rate for MZ twins than for DZ twins suggests genetic influences.

Two concordance rates are commonly calculated: the pairwise and the probandwise concordance rate. In the pairwise concordance rate, each twin pair is counted as one unit. The concordance rate is then simply equal to the proportion of twin pairs in the total sample in which both twins have the disorder. The proband is the member of a twin pair who qualified the pair for inclusion in the study. It is possible for both members of a twin pair

to be independently selected. In the probandwise concordance rate, these pairs would be counted twice. For example, assume a total sample of 10 twin pairs. If there would be 6 twin pairs where both members of the pair would have the disease, the pairwise concordance rate would be $6/10 = 0.6$. Now assume that 2 of the 6 twin pairs with two affected twins were independently selected for the study. These pairs would be counted twice, and the 4 other pairs with a single proband once. This gives as the numerator of the probandwise concordance rate $2 \times 2 + 4 = 8$. The denominator equals the sum of the numerator plus the discordant twin pairs counted once. In our example, the pairwise probandwise concordance rate would therefore equal $8/(8 + 4) = 0.67$.

Conditional Independence

Stochastic independence is a principal assumption in many models. Although often restrictive, it is very convenient because it is a special case of association. Without assuming independence, the covariance or correlation (dependence) structure of the observations has to be specified. Conditional independence is a natural way of relaxing the assumption of independence. Regression models (*see Multiple Linear Regression*) can be regarded as models of conditional independence, especially when the values of the covariates are not specified in advance but are, together with the values of the outcomes, subject to the vagaries of the sampling and data-generation processes.

Variables that induce (by conditioning) independence of outcome variables need not be observed. For example, scores on the sections of a test are usually correlated. Although the subjects have strengths and weaknesses in the different domains of the test represented by its sections, those who obtain high scores on one section tend to obtain high scores also on other sections. However, the correlations among the scores are reduced substantially if considered over the subjects with a specific value of a background variable, such as past performance or the dominant latent ability (trait). Indeed, many models for educational scores are based on conditional independence of the responses given the subject's ability [3]. With continuous (normally distributed) outcomes, **factor analysis** [2], postulates models in which the outcomes are conditionally independent given a few **latent variables**.

According to [1], every probability (statement) is conditional, either explicitly or because of the context and assumptions under which it is formulated. By the same token, every distribution is conditional, and therefore every statement of independence, referring to distributions, is conditional, and has to be qualified by the details of conditioning. Two random variables that are conditionally independent given the value of a third variable need not be conditionally independent given the value of a fourth variable. When they are independent, additional conditioning does not upset their (conditional) independence.

Operating with conditional distributions is relatively easy, facilitated by the identity

$$f(x, y|z) = \frac{f(x, y, z)}{f(z)}, \quad (1)$$

where f is the generic notation for a density or probability of the (joint) distribution given by its arguments. Hence, conditional independence of X and Y , given Z , is equivalent to

$$f(x, y, z)f(z) = f(x, z)f(y, z). \quad (2)$$

However, one of the difficulties with conditional distributions is that their densities or probabilities often have forms very different from their parent (unconditional, or less conditional) distributions. The normal and multinomial distributions are important exceptions (*see Catalogue of Probability Density Functions*).

Suppose y and $\mathbf{x}$ are jointly normally distributed with mean vector $\mu = (\mu_y, \mu_x)$ and variance matrix

$$\Sigma = \begin{pmatrix} \sigma_y^2 & \sigma_{y,x} \\ \sigma_{x,y} & \Sigma_x \end{pmatrix}. \quad (3)$$

If the values of $\mathbf{x}$ are regarded as fixed the outcomes y are associated with a univariate random sample $(y_i; \mathbf{x}_i)$, $i = 1, \dots, n$. They appear to be dependent, as similar values of $\mathbf{x}$ are associated with similar values of y . However, after conditioning on $\mathbf{x}$,

$$(y|\mathbf{x}) \sim \mathcal{N}(\mu_y + \sigma_{y,x} \Sigma_x^{-1}(\mathbf{x} - \mu_x), \sigma_y^2 - \sigma_{y,x} \Sigma_x^{-1} \sigma_{x,y}), \quad (4)$$

the outcomes are *conditionally* independent given $\mathbf{x}$, although their expectations depend on $\mathbf{x}$. The property of the normal distribution that the conditional distribution of $(y|\mathbf{x})$ belongs to the same class as the distributions of y and $(y, \mathbf{x})$ without conditioning is not shared by other classes of distributions. Together with the closed form of the density of the normal distribution, and its closure with respect to addition, this makes the normal distribution the assumption of choice in many analyses.

Thus far, we were concerned with conditional independence in connection with observational units. A related area of statistical research is conditional independence of variables without such a reference. Well-established examples of this are Markov processes, (*see Markov Chains*) [4], and **time series** processes in general.

2 Conditional Independence

In Markov processes, a sequence of variables indexed by discrete or continuous time t , X_t , has the property that variables X_{t_1} and X_{t_3} are conditionally independent given an intermediate variable X_{t_2} , $t_1 < t_2 < t_3$. The concept of conditional independence is essential in the definitions of other time series models, such as autoregressive and moving-average and their combinations, because they involve (residual) contributions independent of the past.

Search for conditional independence is an important preoccupation in many applications, because it enables a simpler description or explanation of and better insight into the studied processes. In graphical models, [5], sets of random vectors are represented by graphs in which *vertices* (variables) V are connected (associated) by *edges* E . A graph is defined as $G = (V, E)$. An important convention supporting

the interpretation of such graphs is that two sets of variables, A and B , are conditionally independent given C , if and only if there is no connection between the vertices corresponding to A and B after all the vertices that involve a vertex from C are erased. A complex graph is much easier to study through sets of such conditionally independent and conditioning variables. The edges may be associated with arrows that represent the direction of causality.

A simple example is drawn in Figure 1. It represents the graph

$$(\{A, B, C, D, E\}, \{AC, AD, BC, CD, CE\}). \quad (5)$$

The circles A–E represent random variables, and lines are drawn between variables that are not conditionally independent. By removing all the lines that connect C with the other variables, B and E are not connected with A or D ; the random vectors and variables $\{A, D\}$, $\{B\}$, and $\{E\}$ are mutually conditionally independent given C .

Conditional Standard Errors of Measurement

Introduction

Errors of measurement for test scores generally are viewed as random and unpredictable. Measurement errors reduce the usefulness of test scores and limit the extent to which test results can be generalized. Conditional standard errors of measurement (conditional SEMs) index the amount of measurement error involved when measuring a particular person's proficiency using a test. The Standards for Educational and Psychological Testing (AERA, APA, & NCME, 1999) recommends that conditional SEMs be reported by test publishers. Conditional SEMs can be used to construct a **confidence interval** on the score an individual earns and serve as one approach for reporting information about reliability.

Theoretically, conditional SEMs are conditioned on persons. For practical reasons, the reported conditional SEMs usually are conditioned on observed scores, because it is often impractical to report different conditional SEMs for people with the same observed test score. Many approaches for estimating conditional SEMs are based on three test theories: **classical test theory (CTT)**, **item response theory (IRT)**, and **generalizability theory (GT)**. These test theories make various assumptions about measurement errors. In this entry, conditional SEMs based on CTT and GT are considered in detail.

Classical Test Theory

Under classical test theory (Feldt & Brennan, [6]), the assumption is made that the observed score (X) is composed of a true score (T) and an error score (E) and $X = T + E$; test forms are *classically parallel*; correlation with an external criterion is the same for all parallel forms, and the expected error scores across test forms or populations of examinees are zero (i.e., $1/K \sum_{f=1}^K E_f = 0$, $1/N \sum_{p=1}^N E_p = 0$, with K being number of test forms and N number of examinees in the population).

For classically parallel forms the expected values and variances of the observed scores are assumed identical across forms. These assumptions are often

relaxed in practice. For *tau-equivalent forms*, the same expected scores are assumed across forms, but such forms are allowed to have different variances. For *essentially tau-equivalent forms*, expected scores across forms are allowed to differ by a constant and variances can differ across forms. For *congeneric forms*, expected scores are assumed to be linearly related, but true and error score variances can be different. For *classically congeneric forms*, error variance is assumed to follow classical theory, in addition to the congeneric forms assumptions (see **Tau-Equivalent and Congeneric Measurements**).

Based on these assumptions, a framework of estimating reliability and standard errors (both conditional and total) was developed. In the following discussion, different methods of estimating conditional SEMs using classical test theory and its extensions are presented.

Thorndike and Mollenkopf Approaches

Thorndike [19] proposed a method to estimate conditional SEMs, assuming tau-equivalent forms. Let X_1 be the observed score on the first half of a test form and X_2 the second half of the test form. The observed scores can be decomposed as

$$\begin{aligned} X_1 &= T + E_1 + c_1 \\ X_2 &= T + E_2 + c_2, \end{aligned} \quad (1)$$

where c_1 and c_2 are constants under tau-equivalent forms assumption. The theory is relatively straightforward: the variance of half-test difference ($\text{Var}(X_1 - X_2)$) equals the error variance of the total test ($\text{Var}(X_1 + X_2)$), because errors are assumed to be uncorrelated. That is,

$$\text{Var}(X_1 - X_2) = \text{Var}(X_1 + X_2). \quad (2)$$

By grouping individuals into a series of short intervals and estimating the total score and the variance of difference scores, the conditional SEMs for all intervals can be estimated.

For extreme intervals where not many examinees score, Thorndike's method can produce erratic estimates of conditional SEMs. Mollenkopf [18] proposed a regression technique to smooth out such irregularities and to make the estimates more stable. Still assuming tau-equivalent forms, consider the following quantity for a person:

$$Y_p = [(X_1 - X_2)_p - (\bar{X}_1 - \bar{X}_2)]^2, \quad (3)$$

2 Conditional Standard Errors of Measurement

when $\bar{X}_1$ is the mean of X_1 and $\bar{X}_2$ the mean of X_2 . The mean of this quantity estimates the variance of the half-test difference, which is an estimate for the total test error variance for the group. In the regression, Y is considered the dependent variable being predicted by $X_1 + X_2$ using polynomial regression. (see **Polynomial Model**) One potential complication with this method is to choose a certain degree of the polynomial. The lowest degree that fits the data is recommended in practice [6].

Lord's Binomial Error Model

Perhaps the best-known approach of calculating conditional SEMs was proposed by Lord [13, 14] based on the binomial error model. Under the binomial error model, each test form is regarded as a random set of n independent and dichotomously scored items. Each examinee is assumed to have a true proportion score (ϕ_p); the error for an individual p can therefore be defined as $X_p - n(\phi_p)$. Under such a conceptualization, the error variance conditional on a person over the population of test forms is

$$\sigma_{E.X_p}^2 = n(\phi_p)(1 - \phi_p). \quad (4)$$

Using the estimate of ϕ_p obtained through observed scores, $\hat{\phi}_p = X_p/n$, the estimate of the error variance for a person can be calculated:

$$\hat{\sigma}_{E.X_p}^2 = \frac{(n - X_p)X_p}{n - 1}. \quad (5)$$

The square root of this quantity yields the estimated conditional SEM for the person p .

By definition, persons with the same observed score on a given test have the same error variance under this model. One potential problem with this error model is that it fails to address the fact that test developers construct forms to be more similar to one another than would be expected if items were randomly sampled from a large pool of items. Therefore, this estimator typically produces overestimates of the conditional SEMs. Keats [8] proposed a correction factor for this binomial error model that proved to be quite effective.

Stratified Binomial Error

Feldt [5] modified Lord's binomial error model. His approach assumes that the test consists of a stratified

random sample of items where the strata are typically based on content classifications. Let $n_1, n_2, \dots$ be the number of items drawn from each stratum and $X_{p1}, X_{p2}, \dots$ be the observed score of person p on strata $1, 2, \dots$. In this case, the estimated total test error variance for person p is

$$\hat{\sigma}_{E.X_p}^2 = \sum_{h=1}^m \frac{(n_h - X_{ph})X_{ph}}{n_h - 1}. \quad (6)$$

Errors are assumed independent across strata and m is the total number of strata on the test.

When the number of items associated with any particular stratum is small, it can lead to instability in estimating the conditional SEMs using this method. Furthermore, for examinees with the same observed scores, the estimates of their conditional SEMs may be different, which might pose practical difficulties in score reporting.

Strong True Score Theory

Strong true score models can also be considered extensions of the classical test theory. In addition to assuming a binomial-related model for error score, typically a distributional form is assumed for true proportion-correct scores (ϕ). The most frequently used distribution form for true proportion scores is the beta distribution (see **Catalogue of Probability Density Functions**) whose random variable ranges from 0 to 1. The conditional error distribution $\Pr(X = i | \phi)$ is typically assumed to be binomial or compound binomial. Under these assumptions, the observed score then will follow a beta-binomial or compound beta-binomial distribution ([9], [15], and [16]).

Using Lord's two-term approximation of the compound binomial distribution, a general form of the error variance [15] can be estimated using

$$\hat{\sigma}_{E|x_p}^2 = \frac{x_p(n - x_p)}{n - 1} \times \left[1 - \frac{n(n - 1)S_{\bar{X}_i}^2}{\hat{\mu}_X(n - \hat{\mu}_X) - S_{X_p}^2 - nS_{\bar{X}_i}} \right]. \quad (7)$$

In 7, x_p is an observed score, $S_{\bar{X}_i}^2$ the observed variance of item difficulties and $S_{X_p}^2$ the observed variance of all examinees.

Generalizability Theory

Generalizability theory also assumes that observed test scores are composed of true score and error scores. A fundamental difference between generalizability theory and classical test theory is that under CTT, multiple sources of errors are confounded whereas under GT, errors are disentangled. GT typically involves two studies: G (*generalizability*) studies and D (*decision*) studies. The purpose of a G study is to obtain estimates of variance components associated with a universe of admissible observations. D studies emphasize the estimation, use, and interpretation of variance components for decision-making with well-specified measurement procedures [4]. **Linear models and Analysis Of Variance (ANOVA)** approaches are used to estimate errors and reliability.

Depending on the sources of errors in which the investigator is interested, different designs can be chosen for G and D studies. The simplest G study design is the person cross item ($p \times i$) design. For this design, all the examinees take the same set of items. Under the $p \times i$ design, an observed score is defined as $X_{pi} = \mu + v_p + v_i + v_{pi}$, where μ is the grand mean in the population and v_p , v_i , and v_{pi} are uncorrelated error effects related to the person, the item, and the person cross the item. The variances of these effects ($\sigma^2(p)$, $\sigma^2(i)$, and $\sigma^2(pi)$) are called *variance components* and are of major concern in GT. Reliability and standard errors can be calculated from estimated variance components.

The corresponding D study is the $p \times I$ design. The linear decomposition of an examinee's average score, X_{pI} , over n' items, is $X_{pI} = \bar{X}_p = \mu + v_p + v_I + v_{pI}$, where the n' items for the D study are considered 'randomly parallel' of the n items in the G study. Under GT, by convention, average scores over a sample of conditions are indicated by uppercase letters. Other more complicated designs for both studies exist and are not further described in this entry. Brennan [4] gives a detailed description of different designs and the linear models related to each of the designs.

There are two kinds of errors under GT: *absolute error* and *relative error*. Both error variances can be defined in terms of the variance components obtained from a G study and the sample sizes used in a D study (n'). Absolute error refers to the difference between a person's observed score and universe score ($\Delta_{pI} =$

$X_{pI} - \mu_p$); relative error refers to the difference between a person's observed deviation score and universe deviation score ($\delta_{pI} = (X_{pI} - \mu_I) - (\mu_p - \mu)$). It can be shown that the absolute error is always larger or equal to the relative error, depending on the design of the D study. Accordingly, there are also two kinds of conditional SEMs in GT: Conditional absolute SEM and conditional relative SEM.

Brennan [4] argued that depending on the designs involved in GT, conditional SEMs are defined or estimated somewhat differently. Because of the complications associated with unbalanced designs, the conditional SEMs are only considered for the balanced design in this entry. A balanced design has no missing data, and the sample size is constant for each level of a nested facet.

Conditional Absolute Standard Error of Measurement

Conditional absolute SEM is straightforward with balanced designs: it is the standard error of the within-person mean. For a $p \times i$ design, absolute error for person p is $\Delta_p = X_{pI} - \mu_p$, the difference between the person's observed mean score across items (X_{pI}) and the mean score for the universe of items (μ_p). The associated error variance is:

$$\sigma^2(\Delta_p) = \text{var}(X_{pI} - \mu_p | p), \quad (8)$$

which is the variance of the mean over the number of items (n') for a D study for person p . An unbiased estimator is

$$\hat{\sigma}^2(\Delta_p) = \frac{\sum_i (X_{pi} - X_{pI})^2}{n'(n - 1)}, \quad (9)$$

the square root of which is an estimator of the conditional absolute SEM.

When all items are scored dichotomously and the number of items is the same for G and D studies (i.e., $n = n'$), the conditional absolute SEM is the same as Lord's conditional SEM. The extension of estimating conditional absolute SEMs for multifacet designs are illustrated in Brennan ([4], pp. 164–165).

Conditional Relative Standard Error of Measurement

Relative error for person p is $\delta_p = (X_{pI} - \mu_I) - (\mu_p - \mu)$, the difference between observed deviation

4 Conditional Standard Errors of Measurement

score and universe deviation score. Using results from Jarjoura [7], Brennan [3] showed that when the sample size for persons is large, an approximate estimator of the conditional relative SEM is

$$\hat{\sigma}(\delta_p) \doteq \sqrt{\hat{\sigma}^2(\Delta_p) + \frac{\hat{\sigma}^2(i)}{n'} - \frac{2\text{cov}(X_{pi}, X_{Pi|p})}{n'}}, \quad (10)$$

where $\text{cov}(X_{pi}, X_{Pi|p})$ is the observed covariance over items between examinee p 's item scores and the item mean scores. The observed covariance is not necessarily 0.

For multifacet designs, estimators exist for estimating the conditional relative SEMs, but they are rather complicated ([4], pp. 164–165). For practical use, the following formula often provides an adequate estimate:

$$\hat{\sigma}(\delta_p) = \sqrt{\hat{\sigma}^2(\Delta_p) - [\hat{\sigma}^2(\Delta) - \hat{\sigma}^2(\delta)]}. \quad (11)$$

Relationship Between Conditional SEMs Based on GT and CTT

Empirical investigation of the methods suggests that the estimates of conditional SEMs are fairly close to each other when these methods are applied to standardized achievement tests [2], [17]. These methods strongly support the conclusion that conditional SEMs vary as a curvilinear function of the observed score and the true score, on the raw score metric.

When scores are dichotomously scored and the sample sizes are the same for G and D studies, the conditional SEMs calculated using Lord's binomial error model yields the same result as the conditional absolute SEMs, even when the underlying test models differ. The conditional relative SEMs are harder to estimate [4], [12].

Score Scales

Number-correct raw scores on standardized tests typically are transformed to scale scores. Such transformations are often nonlinear. Some examples of nonlinear transformations are developmental standard scores, stanines, ACT scores, and SAT scores. The conditional SEMs calculated typically need to be on the same score scale on which

the test score is reported. To convert raw scores to scale scores, rounding and truncation are often involved.

On the raw score scale, the conditional SEM tends to be large for middle scores and small for extreme scores. If the raw-to-scale score transformation is linear, then the scale score reliability will remain the same and the conditional SEM of the scale scores is a multiple of the conditional SEM of raw scores and the relative magnitude stays the same. However, a nonlinear transformation can change the relative magnitude of conditional SEMs. For example, a transformation that stretches the two ends and compresses the middle of the score distribution can make the conditional SEM fairly consistent across the score scale. With an even more extreme transformation, the conditional SEMs can be made relatively large at the two extremes and small in the middle [10].

Practical Applications

The Standards for Educational and Psychological Testing requires that the conditional SEMs be reported (AERA, APA, & NCME, [1], p. 35, Standard 2.14). It is recommended that

'conditional standard errors of measurement should be reported at several score levels if consistency cannot be assumed. Where cut scores are specified for selection or classification, the standard errors of measurement should be reported in the vicinity of each cut score.'

Conditional SEMs provide a 'confidence band' for the observed test score an individual earns.

Because of the requirements in the Test Standards, testing programs report conditional SEMs. When the ACT Assessment was rescaled in 1989 [11], an arcsine transformation was applied on the raw scores, which resulted in conditional SEMs of the scale scores being relatively constant across all score levels for all the subtests.

For some other test batteries, such as SAT scores, conditional SEMs are not forced to be constant across the score levels. Instead, the testing programs typically report conditional SEMs in their test manuals for a number of score levels.

Summary and Conclusion

Conditional SEMs provide important information on the amount of error in observed test scores. Many approaches have been proposed in the literature to estimate conditional SEMs. These approaches are based on different test theory models and assumptions. However, these methods typically produce fairly consistent results when applied to standardized achievement tests. There are no existing rules stating which method to use in the estimation of conditional SEMs. Practitioners can choose a certain method that aligns the best with the assumptions made and the characteristics of their tests. On the raw score scale, conditional SEMs are relatively large in magnitude at the two ends and small in the middle. However, conditional SEMs for scale scores can take on a variety of forms depending on the function of raw-to-scale score transformations that are used.

Confidence Intervals

Behavioral scientists have long been criticized for their overreliance on null hypothesis significance testing in the statistical analysis of their data [4, 13, 17, 21, 22, 28]. A null hypothesis is a precise statement about one or more population parameters from which, given certain assumptions, a probability distribution for a relevant sample statistic can be derived (*see Sampling Distributions*). As its name implies, a null hypothesis is usually a hypothesis that no real effect is present (two populations have identical means, two variables are not related in the population, etc.). A decision is made to reject or not reject such a null hypothesis on the basis of a significance test applied to appropriately collected sample data. A significant result is taken to mean that the observed data are not consistent with the null hypothesis, and that a real effect is present. The significance level represents the conditional probability that the process would lead to the rejection of the null hypothesis given that it is, in fact, true (*see Classical Statistical Inference: Practice versus Presentation*).

Critics have argued that rejecting or not rejecting a null hypothesis of, say, no difference in population means, does not constitute a full analysis of the data or advance knowledge very far. They have implored researchers to report other aspects of their data such as the size of any observed effects. In particular, they have advised researchers to calculate and report confidence intervals for effects of interest [22, 34]. However, it would be a mistake to believe that by relying more on confidence intervals, behavioral scientists were turning their backs on significance testing. Confidence intervals can be viewed as a generalization of the null hypothesis significance test, but in order to understand this, the definition of a null hypothesis has to be broadened somewhat. It is, in fact, possible for a null hypothesis to specify an effect size other than zero, and such a hypothesis can be subjected to significance testing provided it allows the derivation of a relevant sampling distribution. To distinguish such null hypotheses from the more familiar null hypothesis of no effect, the term 'nil hypothesis' was introduced for the latter [6]. Whilst the significance test of the nil null hypothesis indicates whether the data are consistent with a hypothesis that says

there is no effect (or an effect of zero size), a confidence interval indicates all those effect sizes with which the data are and are not consistent.

The construction of a confidence interval will be introduced by considering the estimation of the mean of a normal population of unknown variance from the information contained in a simple random sample from that population. The formula for the confidence interval is a simple rearrangement of that of the single sample *t* Test (*see Catalogue of Parametric Tests*):

$$\bar{X} + t_{0.025, n-1} \left(\frac{\hat{s}}{\sqrt{n}} \right) \leq \mu \leq \bar{X} + t_{0.975, n-1} \left(\frac{\hat{s}}{\sqrt{n}} \right) \quad (1)$$

where $\bar{X}$ is the sample mean, $\hat{s}$ is the unbiased sample standard deviation, n is the sample size, $(\hat{s}/\sqrt{n})$ is an estimate of the standard error of the mean, and $t_{0.025, n-1}$ and $t_{0.975, n-1}$ are the critical values of *t* with $n - 1$ degrees of freedom that cut off the bottom and top 2.5% of the distribution respectively. This is the formula for a 95% confidence interval for the population mean of a normal distribution whose standard deviation is unknown. In repeated applications of the formula to simple random samples from normal populations, the constructed interval will contain the true population mean on 95% of occasions, and not contain it on 5% of occasions. Intervals for other levels of confidence are easily produced by substituting appropriate critical values. For example, if a 99% confidence interval was required, $t_{0.005, n-1}$ and $t_{0.995, n-1}$ would be employed.

The following example will serve to illustrate the calculation. A sample of 20 participants was drawn at random from a population (assumed normal) and each was measured on a psychological test. The sample mean was 283.09 and the unbiased sample standard deviation was 51.42. The appropriate critical values of *t* with 19 degrees of freedom are -2.093 and $+2.093$. Substituting in (1) gives the 95% confidence interval for the mean of the population as $259.02 \leq \mu \leq 307.16$. It will be clear from the formula that the computed interval is centered on the sample mean and extends a number of estimated standard errors above and below that value. As sample size increases, the exact number of estimated standard errors above and below the mean approaches 1.96 as the *t* distribution approaches the standardized normal distribution. Of course, as sample size increases, the estimated standard error of the mean decreases

2 Confidence Intervals

and the confidence interval gets narrower, reflecting the greater accuracy of estimation resulting from a larger sample.

The Coverage Interpretation of Confidence Intervals

Ninety five percent of intervals calculated in the above way will contain the appropriate population mean, and 5% will not. This property is referred to as ‘coverage’ and it is a property of the procedure rather than a particular interval. When it is claimed that an interval contains the estimated population mean with 95% confidence, what should be understood is that the procedure used to produce the interval will give 95% coverage in the long run. However, for any particular interval that has been calculated, it will be either one of the 95% that contain the population mean or one of the 5% that do not. There is no way of knowing which of these two is true. According to the frequentist view of probability (*see Probability: Foundations of*) from which the method derives [24], for any particular confidence interval the population is either included or not included in it. The probability of inclusion is therefore either 1 or 0. The confidence interval approach does not give the probability that the true population mean will be in the particular interval constructed, and the term ‘confidence’ rather than ‘probability’ is employed to reinforce the distinction. Despite the claims of the authors of many elementary textbooks [8], significance tests do not result in statements about the probability of the truth of a hypothesis, and confidence intervals, which derive from the same statistical theory, cannot do so either. The relationship between confidence intervals and significance testing is examined in the next section.

The Significance Test Interpretation of Confidence Intervals

The lower limit of the 95% confidence interval calculated above is 259.02. If the sample data were used to conduct a two-tailed one sample t Test at the 0.05 significance level to test the null hypothesis that the true population mean was equal to 259.02, it would yield a t value that was just nonsignificant. However, any null hypothesis that specified that the population mean was a value less than 259.02 would

be rejected by a test carried out on the sample data. The situation is similar with the upper limit of the calculated interval, 307.16. The term ‘plausible’ has been applied to values of a population parameter that are included in a confidence interval [10, 29]. According to this usage, the 95% confidence interval calculated above showed any value between 259.02 and 307.16 to be a ‘plausible’ value for the mean of the population, as such values would not be rejected by a two-tailed test at the 0.05 level carried out on the obtained sample data.

One-sided Confidence Intervals

In some circumstances, interest is focused on estimating only the highest (or lowest) plausible value for a population parameter. The distinction between two-sided intervals and one-sided intervals mirrors that between two-tailed and one-tailed significance tests. The formula for one of the one-sided 95% confidence intervals for the population mean, derived from the one-tailed single sample t Test is:

$$-\infty \leq \mu \leq \bar{X} + t_{0.950, n-1} \left(\frac{\hat{s}}{\sqrt{n}} \right) \quad (2)$$

Applying (2) to the example data above yields:

$$-\infty \leq \mu \leq 302.97 \quad (3)$$

In the long run, intervals calculated in this way will contain the true population value for 95% of appropriately collected samples, but they are not popular in the behavioral sciences for the same reasons that one-tailed tests are unpopular (*see Classical Statistical Inference: Practice versus Presentation*).

Central and Noncentral Confidence Intervals

The two-sided and one-sided 95% confidence intervals calculated above represent the extremes of a continuum. With the two-sided interval, the 5% rejection region of the significance test was split equally between the two tails giving limits of 259.02 and 307.16. In the long run, such intervals are exactly as likely to miss the true population mean by having a lower bound that is too high as by having an upper bound that is too low. Intervals with this property are known as ‘central’. However, with the

one-sided interval, which ranged from $-\infty$ to 302.97, it is impossible for the interval to lie above the population mean, but in the long run 5% of such intervals will fall below the population mean. This is the most extreme case of a noncentral interval.

It is possible to divide the 5% rejection region in an infinite number of ways between the two tails. All that is required is that the tails sum to 0.05. If the lower rejection region was made to be 1% and the upper region made to be 4% by employing $t_{0.010, n-1}$ and $t_{0.960, n-1}$ as the critical values, then 95% of intervals calculated in this way would include the true population mean and 5% would not. Such intervals would be four times more likely to miss the population mean by being too low than by being too high.

Whilst arguments for employing noncentral confidence intervals have been put forward in other disciplines [15], central confidence intervals are usually employed in the behavioral sciences. In a number of important applications, such as the construction of confidence intervals for population means (and their differences), central confidence intervals have the advantage that they are shorter than noncentral intervals and therefore give the required level of confidence for the shortest range of plausible values.

The Confidence Interval for the Difference Between Two Population Means

If the intention is to compare means, then the appropriate approach is to construct a confidence interval for the difference in population means using a rearrangement of the formula for the two independent samples t Tests (*see Catalogue of Parametric Tests*):

$$\begin{aligned}
 & (\bar{X}_1 - \bar{X}_2) + t_{0.025, n_1+n_2-2} \\
 & \times \sqrt{\left(\frac{(n_1-1)\hat{s}_1^2 + (n_2-1)\hat{s}_2^2}{n_1+n_2-2} \right) \left(\frac{1}{n_1} + \frac{1}{n_2} \right)} \\
 & \leq \mu_1 - \mu_2 \leq (\bar{X}_1 - \bar{X}_2) + t_{0.975, n_1+n_2-2} \\
 & \times \sqrt{\left(\frac{(n_1-1)\hat{s}_1^2 + (n_2-1)\hat{s}_2^2}{n_1+n_2-2} \right) \left(\frac{1}{n_1} + \frac{1}{n_2} \right)} \quad (4)
 \end{aligned}$$

where $\bar{X}_1$ and $\bar{X}_2$ are the two sample means, $\hat{s}_1$ and $\hat{s}_2$ are the unbiased sample standard deviations, and n_1 and n_2 are the two sample sizes. This is

the formula for the 95% confidence interval for the difference between the means of two normal populations, which are assumed to have the same (unknown) variance. When applied to data from two appropriately collected samples, over the course of repeated application, the upper and lower limits of the interval will contain the true difference in population means for 95% of those applications. The formula is for a central confidence interval that is equally likely to underestimate as overestimate the true difference in population means. Since the sampling distribution involved is symmetrical, this is the shortest interval providing 95% confidence.

If (4) is applied to the sample data that were introduced previously ($\bar{X}_1 = 283.09$, $\hat{s}_1 = 51.42$, and $n_1 = 20$) and to a second sample ($\bar{X}_2 = 328.40$, $\hat{s}_2 = 51.90$, and $n_2 = 21$), the 95% confidence interval for the difference in the two population means ranges from -77.96 to -12.66 (which is symmetrical about the observed difference between the sample means of -45.31). Since this interval does not contain zero, the difference in population means specified by the nil null hypothesis, it is readily apparent that the nil null hypothesis can be rejected at the 0.05 significance level. Thus, the confidence interval provides all the information provided by a two-tailed test of the nil null hypothesis at the corresponding conventional significance level.

In addition, the confidence interval implies that a two-tailed independent samples t Test carried out on the observed data would not lead to the rejection of any null hypothesis that specified the difference in population means was equal to a value in the calculated interval, at the 0.05 significance level. This information is not provided by the usual test of the nil null hypothesis, but is a unique contribution of the confidence interval approach. However, the test of the nil null hypothesis of no population mean difference yields an exact P value for the above samples of 0.008. So the nil null hypothesis can be rejected at a stricter significance level than the 0.05 implied by the 95% confidence interval. So whilst the confidence interval approach provides a test of all possible null hypotheses at a single conventional significance level, the significance testing approach provides a more detailed evaluation of the extent to which the data cast doubt on just one of these null hypotheses.

If, as in this example, all the 'plausible' values for the difference in the means of two populations are of the same sign, then Tukey [32] suggests that

it is appropriate to talk of a ‘confident direction’ for the effect. Here, the 95% confidence interval shows that the confident direction of the effect is that the first population mean is less than the second.

The Confidence Interval for the Difference Between Two Population Means and Confidence Intervals for the Two Individual Population Means

The 95% confidence interval for the mean of the population from which the first sample was drawn has been previously shown to range from 259.03 to 307.16. The second sample yields a 95% confidence interval ranging from 304.77 to 352.02. Values between 304.77 and 307.16 are common to both intervals and therefore ‘plausible’ values for the means of both populations. The overlap of the two intervals would be visually apparent if the intervals were presented graphically, and the viewer might be tempted to interpret the overlap as demonstrating the absence of a significant difference between the means of the two samples. However, the confidence interval for the difference between the population means did not contain zero, so the two sample means do differ significantly at the 0.05 level. This example serves to illustrate that caution is required in the comparison and interpretation of two or more confidence intervals. Confidence intervals and significance tests derived from the data from single samples are often based on different assumptions from those derived from the data from two (or more) samples. The former, then, cannot be used to determine the results of the latter directly. This problem is particularly acute in repeated measures designs [11, 19] (*see Repeated Measures Analysis of Variance*).

Confidence Intervals and Posterior Power Analysis

The entry on **power** in this volume demonstrates convincingly that confidence intervals cannot by themselves provide a substitute for prospective power analysis. However, they can provide useful insights into why a result was not significant, traditionally the role of posterior power analysis. The fact that a test result is not significant at the 0.05 level means that the nil null effect size lies within the 95%

confidence interval. Is this because there is no real effect or is it because there is a real effect but the study’s sample size was inadequate to detect it? If the confidence interval is narrow, the study’s sample size has been shown to be sufficient to provide a relatively accurate estimate of the true effect size, and, whilst it would not be sensible to claim that no real effect was present, it might confidently be claimed that no large effect was present. If, however, the confidence interval is wide, then this means that the study’s sample size was not large enough to provide an accurate estimate of the true effect size. If, further, the interval ranges from a large negative limit to a large positive limit, then it would be unwise to claim anything except that more information is needed.

Confidence Intervals Based on Approximations to a Normal Distribution

As sample sizes increase, the sampling distributions of many statistics tend toward a normal distribution with a standard error that is estimated with increasing precision. This is true, for example, of the mean of a random sample from some unknown nonnormal population, where an interval extending from 1.96 estimated standard errors below the observed sample mean to the same distance above the sample mean gives coverage closer and closer to 95% as sample size increases. A rough and ready 95% confidence interval in such cases would range from two estimated standard errors below the sample statistic to two above. Intervals ranging from one estimated standard error below the sample statistic to one above would give approximately 68% coverage, and this reasoning lies behind the promotion of mean and error graphs by the editors of some journals [18]. Confidence intervals for population correlation coefficients are often calculated in this way, as Fisher’s z transformation of the sample Pearson correlation (r) tends toward a normal distribution of known variance as sample size increases (*see Catalogue of Parametric Tests*). The procedure leads to intervals that are symmetrical about the transformed sample correlation (z_r), but the symmetry is lost when the limits of the interval are transformed back to r .

These are large sample approximations, however, and some caution is required in their interpretation. The use of the normal approximation to the binomial distribution in the construction of a confidence

interval for a population proportion will be used to illustrate some of the issues.

Constructing Confidence Intervals for the Population Proportion

Under repeated random sampling from a population where the population proportion is π , the sample proportion, p , follows a discrete, binomial distribution (see **Catalogue of Probability Density Functions**), with mean π and standard deviation $\sqrt{\pi(1-\pi)/n}$. As n increases, provided π is not too close to zero or one, the distribution of p tends toward a normal distribution. In these circumstances, $\sqrt{p(1-p)/n}$ can provide a reasonably good estimate of $\sqrt{\pi(1-\pi)/n}$, and an approximate 95% confidence interval for π is provided by

$$p - 1.96\sqrt{\frac{p(1-p)}{n}} \leq \pi \leq p + 1.96\sqrt{\frac{p(1-p)}{n}} \quad (5)$$

In many circumstances, this may provide a serviceable confidence interval. However, the approach uses a continuous distribution to approximate a discrete one and makes no allowance for the fact that $\sqrt{p(1-p)/n}$ cannot be expected to be exactly equal to $\sqrt{\pi(1-\pi)/n}$. Particular applications of this approximation can result in intervals with an impossible limit (less than zero or greater than one) or of zero width (when p is zero or one).

A more satisfactory approach to the question of constructing a confidence interval for a population proportion, particularly when the sample size is small, is to return to the relationship between the plausible parameters included in a confidence interval and statistical significance. According to this, the lower limit of the 95% confidence interval should be that value of the population proportion, π_L , which if treated as the null hypothesis, would just fail to be rejected in the upper tail of a two-tailed test at the 0.05 level on the observed data. Similarly, the upper limit of the 95% confidence interval should be that value of the population proportion, π_U , which if treated as the null hypothesis, would just fail to be rejected in the lower tail of a two-tailed test at the 0.05 level on the observed data. However, there are particular problems in conducting two-tailed tests on a discrete variable like the sample proportion [20]. As a result, the approach taken is to work in terms of one-tailed tests

and to find the value of the population proportion π_L , which if treated as the null hypothesis, would just fail to be rejected by a one-tailed test (in the upper tail) at the 0.025 level on the observed data, and the value π_U , which if treated as the null hypothesis, would just fail to be rejected by a one-tailed test (in the lower tail) at the 0.025 level on the observed data [3].

The approach will be illustrated with a small sample example that leads to obvious inconsistencies when the normal approximation is applied. A simple random sample of Chartered Psychologists is drawn from the British Psychological Society's Register. Of the 20 psychologists in the sample, 18 are female. The task is to construct a 95% confidence interval for the proportion of Chartered Psychologists who are female.

Using the normal approximation method, (5) would yield:

$$\begin{aligned} 0.9 - 1.96\sqrt{\frac{0.9(1-0.9)}{20}} &\leq \pi \leq 0.9 \\ &+ 1.96\sqrt{\frac{0.9(1-0.9)}{20}} \\ 0.77 &\leq \pi \leq 1.03 \end{aligned} \quad (6)$$

The upper limit of this symmetrical interval is outside the range of the parameter. Even if it was treated as 1, it is clear that if this were made the null hypothesis of a one-tailed test at the 0.025 level, then it must be rejected on the basis of the observed data, since if the population proportion of females really was 1, the sample could not contain any males at all, but it did contain two.

The exact approach proceeds as follows. That value of the population proportion, π_L , is found such that under this null hypothesis the sum of the probabilities of 18, 19 and 20 females in the sample of 20 would equal .025. Reference to an appropriate table [12] or statistical package (e.g., Minitab) yields a value of 0.683017. Then, that value of the population proportion, π_U , is found such that under this null hypothesis the sum of the probabilities of 0, 1, 2, ..., 18 females in a sample of 20 would be .025. The desired value is 0.987651.

So the exact 95% confidence interval for the population proportion of females is:

$$0.683017 \leq \pi \leq 0.987651 \quad (7)$$

If a one-tailed test at the 0.025 level was conducted on any null hypothesis that specified that the population proportion was less than 0.683017, it would

be rejected on the basis of the observed data. So also would any null hypothesis that specified that the population proportion was greater than 0.987651.

In contrast to the limits indicated by the approximate method, those produced by the exact method will always lie within the range of the parameter and will not be symmetrical around the sample proportion (except when this is exactly 0.5). The exact method yields intervals that are conservative in coverage [23, 33], and alternatives have been suggested. One approach questions whether it is appropriate to include the full probability of the observed outcome in the tail when computing π_L and π_U . Berry and Armitage [3] favor **Mid-P** confidence intervals where only half the probability of the observed outcome is included. The Mid-P intervals will be rather narrower than the exact intervals, and will result in a rather less conservative coverage. However, in some circumstances the Mid-P coverage can fall below the intended level of confidence, which cannot occur with the exact method [33].

Confidence Intervals for Standardized Effect Size Measures

Effect size can be expressed in a number of ways. In a simple two condition experiment, the population effect size can be expressed simply as the difference between the two population means, $\mu_1 - \mu_2$, and a confidence interval can be constructed as illustrated above. The importance of a particular difference between population means is difficult to judge except by those who are fully conversant with the measurement scale that is being employed. Differences in means are also difficult to compare across studies that do not employ the same measurement scale, and the results from such studies prove difficult to combine in **meta-analyses**. These considerations led to the development of standardized effect size measures that do not depend on the particular units of a measurement scale. Probably the best known of these measures is Cohen's d . This expresses the difference between the means of two populations in terms of the populations' (assumed shared) standard deviation:

$$d = \frac{\mu_1 - \mu_2}{\sigma} \quad (8)$$

Standardized effect size measures are unit-less, and therefore, it is argued, are comparable across

studies employing different measurement scales. A d value of 1.00 simply means that the population means of the two conditions differ by one standard deviation. Cohen [5] identified three values of d (0.2, 0.5, and 0.8) to represent small, medium, and large effect sizes in his attempts to get psychologists to take power considerations more seriously, though the appropriateness of 'canned' effect sizes has been questioned by some [14, 16].

Steiger and Fouladi [31] have provided an introduction to the construction of confidence intervals for standardized effects size measures like d from their sample estimators. The approach, based on noncentral probability distributions, proceeds in much the same way as that for the construction of an exact confidence interval for the population proportion discussed above. For a 95% confidence interval, those values of the noncentrality parameter are found (by numerical means) for which the observed effect size is in the bottom 0.025 and top 0.025 of the sampling distributions. A simple transformation converts the obtained limiting values of the noncentrality parameter into standardized effect sizes. The calculation and reporting of such confidence intervals may serve to remind readers that observed standardized effect sizes are random variables, and are subject to sampling variability like any other sample statistic.

Confidence Intervals and the Bootstrap

Whilst the central limit theorem might provide support for the use of the normal distribution in constructing approximate confidence intervals in some situations, there are other situations where sample sizes are too small to justify the process, or sampling distributions are suspected or known to depart from normality. The **Bootstrap** [7, 10] is a numerical method designed to derive some idea of the sampling distribution of a statistic without recourse to assumptions of unknown or doubtful validity. The approach is to treat the collected sample of data as if it were the population of interest. A large number of random samples are drawn with replacement from this 'population', each sample being of the same size as the original sample. The statistic of interest is calculated for each of these 'resamples' and an empirical sampling distribution is produced. If a large enough number of resamplings is performed, then a 95% confidence interval can be produced directly from these

by identifying those values of the statistic that correspond to the 2.5th and 97.5th percentiles. On other occasions, the standard deviation of the statistic over the 'resamples' is calculated and this is used as an estimate of the true standard error of the statistic in one of the standard formulae. Various ways of improving the process have been developed and subjected to some empirical testing. With small samples or with samples that just by chance are not very representative of their parent population, the method may provide rather unreliable information. Nonetheless, Efron, and Tibshirani [10] provide evidence that it works well in many situations, and the methodology is becoming increasingly popular.

Bayesian Certainty Intervals

Confidence intervals derive from the frequentist approach to statistical inference that defines probabilities as the limits in the long run of relative frequencies (*see* **Probability: Foundations of**). According to this view, the confidence interval is the random variable, not the population parameter [15, 24]. In consequence, when a 95% confidence interval is constructed, the frequentist position does not allow statements of the kind 'The value of the population parameter lies in this interval with probability 0.95'. In contrast, the Bayesian approach to statistical inference (*see* **Bayesian Statistics**) defines probability as a subjective or psychological variable [25, 26, 27]. According to this view, it is not only acceptable to claim that particular probabilities are associated with particular values of a parameter; such claims are the very basis of the inference process. Bayesians use Bayes's Theorem (*see* **Bayesian Belief Networks**) to update their prior beliefs about the probability distribution of a parameter on the basis of new information. Sometimes, this updating process uses elements of the same statistical theory that is employed by a frequentist and the final result may appear to be identical to a confidence interval. However, the interpretation placed on the resulting interval could hardly be more different.

Suppose that a Bayesian was interested in estimating the mean score of some population on a particular measurement scale. The first part of the process would involve attempting to sketch a prior probability distribution for the population mean, showing

what value seemed most probable, whether the distribution was symmetrical about this value, how spread out the distribution was, perhaps trying to specify the parameter values that contained the middle 50% of the distribution, the middle 90%, and so on. This process would result in a subjective prior distribution for the population mean. The Bayesian would then collect sample data, in very much the same way as a Frequentist, and use Bayes's Theorem to combine the information from this sample with the information contained in the prior distribution to compute a posterior probability distribution. If the 2.5th and 97.5th percentiles of this posterior probability distribution are located, they form the lower and upper bounds on the Bayesian's 95% certainty interval [26].

Certain parallels and distinctions can be drawn between the confidence interval of the Frequentist and the certainty interval of the Bayesian. The center of the Frequentist's confidence interval would be the sample mean, but the center of the Bayesian's certainty interval would be somewhere between the sample mean and the mean of the prior distribution. The smaller the variance of the prior distribution, the nearer the center of the certainty interval will be to that of the prior distribution. The width of the Frequentist's confidence interval would depend only on the sample standard deviation and the sample size, but the width of the Bayesian's certainty interval would be narrower as the prior distribution contributes a 'virtual' sample size that can be combined with the actual sample size to yield a smaller posterior estimate of the standard error as well as contribute to the degrees of freedom of any required critical values.

So, to the extent that the Bayesian had any views about the likely values of the population mean before data were collected, these views will influence the location and width of the 95% certainty interval. Any interval so constructed is to be interpreted as a probability distribution for the population mean, permitting the Bayesian to make statements like, 'The probability that μ lies between L and U is X.' Of course, none of this is legitimate to the Frequentist who distrusts the subjectivity of the Bayesian's prior distribution, its influence on the resulting interval, and the attribution of a probability distribution to a population parameter that can only have one value.

If the Bayesian admits ignorance of the parameter being estimated prior to the collection of the sample, then a uniform prior might be specified which says that any and all values of the population parameter are

equally likely. In these circumstances, the certainty interval of the Bayesian and the confidence interval of the Frequentist will be identical in numerical terms. However, an unbridgeable gulf will still exist between the interpretations that would be made of the interval.

Confidence Intervals in Textbooks and Computer Packages

Despite the recognition that they have been neglected in the past, most statistics textbooks for behavioral scientists give rather little space to confidence intervals (compared to significance tests). Smithson has gone some way to filling the gap, though his earlier and more elementary book [29] was less than accurate on a number of topics [9]. His more recent book [30] has a wider range and is more accurate, but it may be at too advanced a level for many behavioral scientists. At the moment, the best texts seem to be coming from medicine. Altman et al. [2] provide a fairly simple introduction to confidence intervals as well as detailed instructions on how to construct them for a number of important parameters. A disc is provided with the text that contains useful programs for computing intervals from raw data or summary statistics. Armitage et al. [1] offer a well-balanced blend of significance tests and confidence intervals at a level that should be accessible to most graduates from the behavioral sciences.

A search of the World Wide Web reveals many sites offering confidence interval calculations for means, variances, correlations, and proportions. These must be approached with some caution as they are not always explicit about just what methodology is being employed. Like the textbooks, the commercial statistical packages commonly used by behavioral scientists tend to neglect confidence intervals compared to significance tests. Packages tend to provide confidence intervals for means and mean differences (including some simultaneous intervals) and for the parameters of regression analysis. There is limited cover of proportions, less of correlations, and hardly any of variances.

It will be some time yet before textbooks and software provide adequate support for the guideline of the American Psychological Association Task Force on Statistical Inference [34] that:

Interval estimates should be given for any effect sizes involving principal outcomes. Provide intervals for correlations and other coefficients of association or variation whenever possible. [p. 599]

Confidence Intervals: Nonparametric

Introduction

Hypothesis testing and constructing **confidence intervals** are among the most common tasks in statistical inference. The two tasks are closely linked. Suppose interest focuses on a parameter θ and a null hypothesis specifies that θ_0 is the value taken by θ . Then, the null hypothesis is rejected by a two-tailed test at significance level α if, and only if, θ_0 is not contained in the $100(1 - \alpha)\%$ central confidence interval for θ . Most methods of forming confidence intervals exploit this relationship, including those described later in this section. However, the first methods we consider – bootstrap methods – are an exception and determine confidence intervals directly from percentiles of a constructed ‘bootstrap’ distribution.

Bootstrap Confidence Intervals

The fundamental steps of the standard **bootstrap** method are as follows.

1. The data are used as a nonparametric estimate of the distribution from which they were drawn. Specifically, suppose the data consist of n observations $y_1, \dots, y_n$, that were drawn from a population with distribution (cumulative distribution function) F . Then, the estimate of F states that every member of the population takes one of the values $y_1, \dots, y_n$ and is equally likely to take any one of these values. Let $\hat{F}$ denote the estimate of F .
2. The sampling method that gave the data is replicated, but using $\hat{F}$ rather than F . Thus, n observations are selected at random *but with replacement* from $y_1, \dots, y_n$. For example, if the original data consist of five values, 4.7, 3.6, 3.9, 5.2, 4.5, then a set of resampled values might be 3.6, 5.2, 3.9, 5.2, 3.9. The resampled values are referred to as a *bootstrap sample*. Let $y_1^*, \dots, y_n^*$ denote the values in the resample.
3. Suppose θ is the population parameter of interest and that $\hat{\theta}$ is the estimate of θ obtained from

$y_1, \dots, y_n$. An estimate of θ , say $\hat{\theta}^*$, is constructed from the bootstrap sample in precisely the same way as $\hat{\theta}$ was obtained from the original sample.

4. Steps 2 and 3 are repeated many times, so as to yield a large number of bootstrap samples, from each of which an estimate $\hat{\theta}^*$ is obtained. The **histogram** of these estimates is taken as an approximation to the *bootstrap probability distribution* of $\hat{\theta}^*$. Bootstrap inferences about θ are based on $\hat{\theta}$ and this distribution.

There are two common methods of forming bootstrap confidence intervals. One is Efron’s *percentile method* [3], which equates **quantiles** of the bootstrap distribution of $\hat{\theta}^*$ to the equivalent quantiles of the distribution of $\hat{\theta}$. The other method is termed the *basic bootstrap method* by Davison and Hinkley [2]. This assumes that the relationship between $\hat{\theta}$ and F is similar to the relationship between $\hat{\theta}^*$ and $\hat{F}$. Specifically, it assumes that the distribution of $\hat{\theta} - \theta$ (where $\hat{\theta}$ is the random quantity) is approximately the same as the distribution of $\hat{\theta}^* - \hat{\theta}$, where $\hat{\theta}^*$ is the random quantity. Let $\theta^*(\alpha)$ denote the α -level quantile of the bootstrap distribution. Then, the percentile method specifies that the $100(1 - 2\alpha)\%$ equal-tailed confidence interval is

$$(\theta^*(\alpha), \theta^*(1 - \alpha))$$

whereas the basic bootstrap method specifies the $100(1 - 2\alpha)\%$ equal-tailed confidence interval as

$$(\hat{\theta} - \{\theta^*(1 - \alpha) - \hat{\theta}\}, \hat{\theta} + \{\hat{\theta} - \theta^*(\alpha)\}).$$

As an example, we will consider a set of data about law school students that has been widely used with the percentile method (e.g., [3], where the data are reported). The data consist of the average scores on two criteria of students entering 15 law schools. One score is LSAT (a national test similar to the Graduate Record Exam) and the other is GPA (undergraduate grade point average). The average scores for each law school are given in Table 1.

The two scores are clearly correlated and have a sample correlation of 0.776. A confidence interval for the population correlation can be determined using bootstrap methods by applying the above procedure, as follows.

1. Define y_i to be the pair of values for the i th law school (e.g., $y_1 = (576, 3.39)$). $\hat{F}$ states that

2 Confidence Intervals: Nonparametric

Table 1 Average LSAT and GPA for students entering 15 law schools

Law school	Average LSAT	Average GPA
1	576	3.39
2	635	3.30
3	558	2.81
4	578	3.03
5	666	3.44
6	580	3.07
7	555	3.00
8	661	3.43
9	651	3.36
10	605	3.13
11	653	3.12
12	575	2.74
13	545	2.76
14	572	2.88
15	594	2.96

each y_i has a probability of $1/15$ of occurring whenever a law school is picked at random.

- As the original sample size was 15, a bootstrap sample is chosen by selecting 15 observations from $\hat{F}$.
- θ is the true population correlation between LSAT and GPA across all law schools. In the original data, the sample correlation between LSAT and GPA is $\hat{\theta} = 0.776$; $\hat{\theta}^*$ is their correlation in a bootstrap sample.
- Steps 2 and 3 are repeated many times to obtain an estimate of the bootstrap distribution of $\hat{\theta}^*$.

For the law school data, we generated 10 000 bootstrap samples of 15 observations and determined the sample correlation for each. A histogram of the 10 000 correlations that were obtained is given in Figure 1.

The histogram shows that the distribution of bootstrap correlations has marked skewness. The sample size is small and a 95% confidence interval for θ would be very wide, so suppose a central 80% confidence interval is required. One thousand of the 10 thousand values of $\hat{\theta}^*$ were less than 0.595 and 1000 were above 0.927, so $\hat{\theta}(0.025) = 0.595$ and $\hat{\theta}(0.975) = 0.927$. The percentile method thus yields $(0.595, 0.927)$ as an 80% confidence interval for θ , while the basic bootstrap method gives an interval of $(0.776 - (0.927 - 0.776), 0.776 + (0.776 - 0.595)) = (0.625, 0.957)$. The difference between the two confidence intervals is substantial because of the skewness of the bootstrap distribution.

Whether the percentile method is to be preferred to the basic bootstrap method, or *vice-versa*, depends upon characteristics of the actual distribution of $\hat{\theta}$. If there is some transformation of $\hat{\theta}$ that gives a symmetric distribution, then the percentile method is optimal. Surprisingly, this is the case even if we do not know what the transformation is. As an example, for the sample correlation coefficient there is a transformation that gives an approximately symmetric distribution (Fisher's $\tanh^{-1}$ transformation). Hence, in the above example the percentile confidence interval is to be preferred to the basic bootstrap interval, even though no transformations were used. Some situations where the basic bootstrap method is optimal are described elsewhere in this encyclopedia (see **Bootstrap Inference**).

A variety of extensions have been proposed to improve the methods, notably the bias-corrected percentile method [4] and the bootstrap- t method [8], which are modifications of the percentile method and basic bootstrap method, respectively. It should be mentioned that the quantity that should be resampled for bootstrapping is not always obvious. For instance, in regression problems the original data

Figure 1 Histogram of bootstrap sample correlations for law school data

points are sometimes resampled (analogous to the above example), while sometimes a regression model is fitted and the residuals from the model are resampled.

Confidence Intervals from Permutation Tests

Permutation tests (*see* **Permutation Based Inference**) and randomization tests (*see* **Randomization Based Tests**) are an appealing approach to hypothesis testing. They typically make fewer distributional assumptions than parametric tests and usually they are just slightly less powerful (*see* **Power**) than their parametric alternatives. Some permutation tests are used to test hypotheses that do not involve parameters, such as whether observations occur at random or whether two variables are independent. This may seem natural, since without parametric assumptions there are few parameters to test. However, quantities such as population means are well-defined without making distributional assumptions and permutation tests may be used to test hypotheses about their value or the difference between two population means, for example. If a permutation test or randomization test can be used to test whether some specified value is taken by a parameter, then the test also enables a confidence interval for the parameter to be constructed.

In a permutation test, the first step is to choose a plausible test statistic for the hypothesis under consideration and to determine the value it takes for the observed data. Then, we find permutations of the data such that the probability of each permutation can be determined under the null hypothesis, H_0 ; usually the permutations are chosen so that each of them is equally probable under H_0 . The value of the test statistic is then calculated for each permutation and a P value is evaluated by comparing the value of the test statistic for the actual data with the probability distribution of the statistic over all the permutations. H_0 is rejected if the observed value is far into a tail of

the probability distribution. In practice, the number of permutations may be so large that the test statistic is only evaluated for a randomly chosen subset of them, in which case the permutation test is often referred to as a randomization test.

Suppose interest centers on a scalar parameter θ and that, for any value θ_0 we specify, a permutation or randomization test can be used to test the hypothesis that θ takes the value θ_0 . Also, assume one-sided tests can be performed and let α_1 be the P value from the test of $H_0: \theta = \theta_L$ against $H_1: \theta > \theta_L$ and let α_2 be the P value from the test of $H_0: \theta = \theta_U$ against $H_1: \theta < \theta_U$. Then, from the relationship between hypothesis tests and confidence interval, (θ_L, θ_U) is a $100(1 - \alpha_1 - \alpha_2)\%$ confidence interval for θ . Usually we want to specify α_1 and α_2 , typically choosing them to each equal 0.025 so as to obtain a central 95% confidence interval. Then, the task is to find values θ_L and θ_U that give these P values.

In practice, the values of θ_L and θ_U are often found by using a simple trial-and-error search based on common sense. An initial ‘guess’ is made of the value of θ_L . Denoting this first guess by L_1 , a permutation test is conducted to test $H_0: \theta = L_1$ against $H_1: \theta > L_1$. Usually between 1000 and 5000 permutations would be used for the test.

Taking account of the P value from this first test, a second guess of the value of θ_L is made and another permutation test conducted. This sequence of trial-and-error continues until the value of θ_L is found to an adequate level of accuracy, (when the P value of the test will be close to α_1). A separate search is conducted for θ_U .

As an example, we consider data from a study into the causes of schizophrenia [12]. Twenty-five hospitalized schizophrenic patients were treated with antipsychotic medication and, some time later, hospital staff judged ten of the patients to be psychotic and fifteen patients to be nonpsychotic. Samples of cerebrospinal fluid were taken from each patient and assayed for dopamine b -hydroxylase activity (nmol/(ml)(hr)/mg). Results are given in Table 2.

Table 2 Dopamine levels of schizophrenic patients

Patients judged psychotic (X):	0.0150	0.0204	0.0208	0.0222	0.0226
	0.0245	0.0270	0.0275	0.0306	0.0320
Patients judged nonpsychotic (Y):	0.0104	0.0105	0.0112	0.0116	0.0130
	0.0145	0.0154	0.0156	0.0170	0.0180
	0.0200	0.0200	0.0210	0.0230	0.0252

4 Confidence Intervals: Nonparametric

The sample totals are $\Sigma x_i = 0.2426$ and $\Sigma y_i = 0.2464$, giving sample means $\bar{x} = 0.02426$ and $\bar{y} = 0.1643$. We assume the distributions for the two types of patients are identical in shape, differing only in their locations, and we suppose that a 95% confidence interval is required for $\theta = \mu_x - \mu_y$, the difference between the population means. The point estimate of θ is $\hat{\theta} = 0.02426 - 0.1643 = 0.00783$.

Let $\theta_L = 0.006$ be the first guess at the lower confidence limit. Then, a permutation test of $H_0: \theta = 0.006$ against $H_1: \theta > 0.006$ must be conducted. To perform the test, 0.006 is subtracted from each measurement for the patients judged psychotic. Denote the modified values by $x'_1, \dots, x'_{10}$ and their mean by $\bar{x}'$. Under H_0 , the distribution of X' and Y are identical, so a natural test statistic is $\bar{x}' - \bar{y}$, which should have a value close to 0 if H_0 is true. Without permutation the value of $\bar{x}' - \bar{y}$ equals $0.00783 - 0.006 = 0.00183$. A permutation of the data simply involves relabeling 10 of the values $x'_1, \dots, x'_{10}, y_1, \dots, y_{15}$ as X -values and relabeling the remaining 15 values as Y -values. The difference between the mean of the relabeled X -values and the mean of the relabeled Y -values is the value of the test statistic for this permutation. Denote this difference by d .

The number of possible permutations is the number of different ways of choosing 10 values from 25 and exceeds 3 million. This number is too large for it to be practical to evaluate the test statistics for all permutations, so instead a random selection of 4999 permutations was used, giving 5000 values of the test statistic when the value for the unpermuted data (0.00183) is included. Nine hundred and twelve of these 5000 values were equal to or exceeded 0.00183, so H_0 is rejected at the 18.24% level of significance. The procedure was repeated using further guesses/estimates of the lower confidence limit. The values examined and the significance levels from the hypothesis tests are shown in Table 3.

The value of 0.0038 was taken as the lower limit of the confidence interval and a corresponding search for the upper limit gave 0.0120 as its estimate. Hence the permutation method gave (0.0038, 0.0120) as the 95% confidence interval for the mean difference in dopamine level between the two types of patient.

A trial-and-error search for confidence limits requires a substantial number of permutations to be performed and is clearly inefficient in terms of computer time. (The above search for just the lower confidence limit required 25 000 permutations). Human input to give the next estimate is also required several times during the search. A much more automated and efficient search procedure is based on the Robbins–Monro process. This search procedure has broad application and is described below under *Distribution-free confidence intervals*. Also for certain simple problems there are methods of determining permutation intervals that do not rely on search procedures. In particular, there are methods of constructing permutation intervals for the mean of a symmetric distribution [9], the difference between the locations of two populations that differ only in their location [9] and the regression coefficient in a simple regression model [5].

Distribution-free Confidence Intervals

The most common distribution-free tests are rank-based tests and methods of forming confidence intervals from some specific rank-based tests are described elsewhere in this encyclopedia. Here we simply give the general method and illustrate it for the Mann–Whitney test, before considering a distribution-free method that does not involve ranks.

The Mann–Whitney test compares independent samples from two populations. It is assumed that the populations have distributions of similar shape but whose means differ by θ . For definiteness, let μ_x and μ_y denote the two means and let $\theta = \mu_x - \mu_y$. The Mann–Whitney test examines the null hypothesis that θ equals a specified value, say θ_0 , testing it against a one- or two-sided alternative hypothesis. (If the null hypothesis is that the population distributions are identical, then $\theta_0 = 0$.) The mechanics of the test are to subtract θ_0 from each of the sample values from the population with mean μ_x . Let $x'_1, \dots, x'_m$ denote these revised values and let $y_1, \dots, y_n$ denote the values from the other sample. The combined set of values $x'_1, \dots, x'_m, y_1, \dots, y_n$, are then ranked from smallest to largest and the sum of the ranks of the x' -values is

Table 3 Sequence of confidence limits and their corresponding significance levels

Estimate of confidence limit:	0.006	0.004	0.003	0.0037	0.0038
Significance level:	18.24	3.04	1.42	2.34	2.54

determined. This sum (or some value derived from its value and the sample sizes) is used as the test statistic. For small sample sizes the test statistic is compared with tabulated critical values and for larger sample sizes an asymptotic approximation is used.

The correspondence between confidence intervals and hypothesis tests can be used to form confidence intervals. For an equal-tailed $100(1 - 2\alpha)\%$ confidence interval, values θ_U and θ_L are required such that $H_0: \theta = \theta_L$ is rejected in favour of $H_1: \theta > \theta_L$ at a P value of α and $H_0: \theta = \theta_U$ is rejected in favour of $H_1: \theta < \theta_U$ at a P value, again, of α . With rank-based tests, there are only a finite number of values that the test statistic can take (rather than a continuous range of values) so it is only possible to find P values that are close to the desired value α . An advantage of rank-based tests, though, is that often there are quick computational methods for finding values θ_L and θ_U that give the P values closest to α . The broad strategy is as follows.

1. For a one-sample test, order the data values from smallest to largest and, for tests involving more than one sample, order each sample separately.
2. Use statistical tables to find critical values of the test statistic that correspond to the P values closest to α .
3. The extreme data values are the ones that increase the P value. For each confidence limit, separately determine the set of data values or combinations of data values that together give a test statistic that equals the critical value or is just in the critical region. The combination of data values that were last to be included in this set determine the confidence interval.

The description of Step 3 is necessarily vague as it varies from test to test. To illustrate the method, we consider the data on schizophrenic patients given in Table 1, and use the Mann–Whitney test to derive a 95% confidence interval for θ , the difference in dopamine b -hydroxylase activity between patients judged psychotic and those judged nonpsychotic. The data for each group of patients have already been ordered according to size, so Step 1 is not needed. The two sample sizes are ten and fifteen and as a test statistic we will use the sum of the ranks of the psychotic patients. From statistical tables (e.g., Table A.7 in [1]), 95 is the critical value at significance level $\alpha = 0.025$ for a one-tailed test of $H_0: \theta = \theta_U$ against $H_1: \theta < \theta_U$. Let $X' = X - \theta_U$. If

the X' -values were all smaller than all the Y -values, the sum of their ranks would be $10(10 + 1)/2 = 55$. As long as forty or fewer of the $X' - Y$ differences are positive, H_0 is rejected, as $40 + 55$ equals the critical value. At the borderline between ‘rejecting’ and ‘not rejecting’ H_0 , the 40th largest $X' - Y$ difference is 0. From this it follows that the upper confidence limit is equal to the 40th largest value of $X - Y$. The ordered data values in Table 1 simplify the task of finding the 40th largest difference. For example, the $X - Y$ differences greater than 0.017 are the following 12 combinations: $X = 0.0320$ in conjunction with $Y = 0.0104, 0.0105, 0.0112, 0.0116, 0.0130$ or 0.0145 ; $X = 0.0306$ in conjunctions with $Y = 0.0104, 0.0105, 0.0112, 0.0116$ or 0.0130 ; $X = 0.0275$ in conjunction with $Y = 0.0104$. A similar count shows that the 40th largest $X - Y$ difference is 0.0120, so this is the upper limit of the confidence interval. Equivalent reasoning shows that the lower limit is the 40th smallest $X - Y$ difference, which here takes the value 0.0035. Hence, the Mann–Whitney test yields (0.0035, 0.0120) as the central 95% confidence interval for θ .

A versatile method of forming confidence intervals is based on the Robbins–Monro process [11]. The method can be used to construct confidence intervals in one-parameter problems, provided the mechanism that gave the real data could be simulated if the parameter’s value were known. We first consider this type of application before describing other situations where the method is useful.

Let θ denote the unknown scalar parameter and suppose a $100(1 - 2\alpha)\%$ equal-tailed confidence interval for θ is required. The method conducts a separate sequential search for each endpoint of the confidence interval. Suppose, first, that a search for the upper limit, θ_U , is being conducted, and let U_i be the current estimate of the limit after i steps of the search. The method sets θ equal to U_i and then generates a set of data using a mechanism similar to that which gave the real data. From the simulated data an estimate of θ is determined, $\hat{\theta}_i$ say. Let $\hat{\theta}^*$ denote the estimate of θ given by the actual sample data. The updated estimate of θ_U , U_{i+1} , is given by

$$U_{i+1} = \begin{cases} U_i - c\alpha/i, & \text{if } \hat{\theta}_i > \hat{\theta}^* \\ U_i + c(1 - \alpha)/i, & \text{if } \hat{\theta}_i \leq \hat{\theta}^* \end{cases} \quad (1)$$

where c is a positive constant that is termed the *step-length constant*.

Table 4 Mark-recapture data for a population of frogs

Sample	Sample size	Number of recaptures	No. of marked frogs in population before sample
1	109	—	—
2	133	15	109
3	138	30	227
4	72	23	335
5	134	47	384
6	72	33	471

The method may be thought of as stepping from one estimate of θ_U to another and c governs the magnitude of the steps. If U_i is equal to the $100(1 - \alpha_i)\%$ point, the expected distance stepped is

$$(1 - \alpha_i)(-c\alpha/i) + \alpha_i c(1 - \alpha)/i = c(\alpha_i - \alpha)/i,$$

which shows that each step reduces the expected distance from θ_U . A predetermined number of steps are taken and the last U_i is adopted as the estimate of θ_U . An independent search is carried out for the lower limit, θ_L . If L_i is the estimate after i steps of the search, then L_{i+1} is found as

$$L_{i+1} = \begin{cases} L_i + c\alpha/i, & \text{if } \hat{\theta}_i < \hat{\theta}^* \\ L_i - c(1 - \alpha)/i, & \text{if } \hat{\theta}_i \geq \hat{\theta}^* \end{cases} \quad (2)$$

This method of forming confidence intervals was developed by Garthwaite and Buckland [7]. They suggest methods of choosing starting values for a search and of choosing the value of the step-length constant. They typically used 5000 steps in the search for an endpoint.

As a practical example where the above method is useful, consider the data in Table 4. These are from a multiple-sample mark-recapture experiment to study a population of frogs [10]. Over a one-month period, frogs were caught in six random samples and, after a sample had been completed, the frogs that had been caught were marked and released. Table 4 gives the numbers of frogs caught in each sample, the number of these captures that were recaptures and the number of frogs that has been marked before the sample. One purpose of a mark-recapture experiment is to estimate the population size, θ say. A point estimate of θ can be obtained by maximum likelihood but most methods of forming confidence intervals require asymptotic approximations that may be inexact. The method based on the Robbins–Monro process can be applied, however, and will give exact intervals. At the

i th step in the search for an endpoint, a population size is specified (U_i or L_i) and equated to θ . Then it is straightforward to simulate six samples of the sizes given in Table 4 and to record the number of recaptures. The estimate of θ based on this resample is $\hat{\theta}_i$ and its value determines the next estimate of the endpoint. Garthwaite and Buckland [7] applied the method to these data and give (932, 1205) as a 95% confidence interval for the population size.

The procedure developed by Garthwaite and Buckland can also be used to form confidence intervals from randomization tests [6]. It is assumed, of course, that the randomization test examines whether a scalar parameter θ takes a specified value θ_0 and that, for any θ_0 , the hypothesis $H_0: \theta = \theta_0$ could be tested against one-sided alternative hypotheses. In the search for the upper limit, suppose U_i is the estimate of the limit after i steps of the Robbins–Monro search. Then the mechanics for a randomization test of the hypothesis $H_0: \theta = U_i$ against $H_1: \theta < U_i$ are followed, except that only a *single* permutation of the data is taken.

Let T_i denote the value of the test statistic from this permutation and let T_1^* denote its value for the actual data (before permutation). The next estimate of the limit is given by

$$U_{i+1} = \begin{cases} U_i - c\alpha/i, & \text{if } T_i > T_1^* \\ U_i + c(1 - \alpha)/i, & \text{if } T_i \leq T_1^* \end{cases} \quad (3)$$

where c is the step-length constant defined earlier and a $100(1 - 2\alpha)\%$ confidence interval is required. A predetermined number of steps are taken and the last U_i is adopted as the estimate of the upper limit. An equivalent search is conducted for the lower limit. An important feature of the search process is that only one permutation is taken at each hypothesized value, rather than the thousands that are taken in unsophisticated search procedures. Typically,

5000 permutations are adequate for estimating each confidence limit.

Most hypothesis tests based on ranks may be viewed as permutation tests in which the actual data values are replaced by ranks. Hence, Robbins–Monro searches may be used to derive confidence intervals from such tests. This approach can be useful if the ranks contain a large number of ties – rank tests typically assume that there are no ties in the ranks and the coverage of the confidence intervals they yield may be uncertain when this assumption is badly violated.

Configural Frequency Analysis

Configural Frequency Analysis and the Person-orientation of Research

Cross-classification of categorical variables can be analyzed from two perspectives. The more frequently used one is *variable-oriented*. Researchers ask questions concerning the relationships among the variables that span the cross-classification. These questions concern, for example, association and dependency structures [5] (*see Contingency Tables*). However, a new perspective, contrasting with the variable-oriented perspective, has emerged since the beginning of the 1990s. This perspective is *person-oriented* [2, 19]. Under this perspective, researchers ask whether subgroups exist that show group-specific patterns of variable relationships.

Consider the following data example [16, 17]. In a study on the development of aggression in adolescents, Finkelstein, von Eye, and Preece [3] asked whether aggression could be predicted from physical pubertal development (PPD). PPD was measured using the Tanner measure. For the following purposes, we use the data from the 1985 and 1987 waves, when the adolescents were 13 and 15 years old. The Tanner measure was scaled to have four levels, with one indicating prepubertal and four indicating physically mature. For the following example, we use the data from 64 respondents. The cross-classification of the 1985 with the 1987 data appears in Table 1.

When looking at Table 1, we notice that, at neither point in time are there adolescents at the level of prepubertal physical development (category 1 does not appear in the table). This is not a surprise, considering the age of the respondents. The cross-classification contains, therefore, only 3×3 instead

of 4×4 cells. We now ask first, from a variable-oriented perspective, whether an association between the measures from 1985 and 1987 exists. We find a Pearson $X^2 = 24.10$, which indicates a significant association ($df = 4; p < 0.01$).

From a person-oriented perspective, we can ask different questions. For example, we ask whether there exist particular patterns that strongly contradict the null hypothesis of independence of the two observations and, thus, shed light on the developmental process. Using Configural Frequency Analysis (CFA; [13, 16, 17]), we show, later in this entry, that particular meaningful patterns stand out.

Concepts and Methods of Configural Frequency Analysis (CFA)

CFA is applied mostly in exploratory contexts. Using CFA, researchers ask whether particular cells stand out in the sense that they contain either more or fewer cases than expected based on *a priori* specified assumptions. If more cases are found than expected, the cell (also called *configuration*) that contains these cases is said to constitute a *CFA type*. If a cell contains fewer cases than expected, it is said to constitute a *CFA antitype*. The *a priori* assumptions are specified in the form of a *base model* (explained in the next paragraph). The null hypothesis for the decision as to whether a cell constitutes a type or an antitype is $H_0 : E[m_i] = e_i$, where i indexes the cells of the cross-classification, e_i is the expected frequency for Cell i , m_i is the observed frequency for Cell i , and E is the expectancy.

To perform a CFA, researchers proceed in five steps. The following sections introduce these five steps.

CFA Base Models and Sampling Schemes

CFA Base Models. The first step involves the selection and specification of a *CFA base model*, and the estimation of the expected cell frequencies. Base models take into account all effects that are NOT of interest for the interpretation of types and antitypes. Types and antitypes then contradict these base models and reflect the processes that the researchers are interested in. Base models can be derived from a number of backgrounds. Most frequently, researchers specify base models in the form of log-frequency

Table 1 Cross-classification of the Tanner scores from 1985 and 1987

		Tanner scores in 1987			
		2	3	4	Totals
Tanner scores in 1985	2	3	17	15	35
	3	0	0	16	16
	4	0	0	13	13
	Totals	3	17	44	64

2 Configurational Frequency Analysis

models (see **Log-linear Models**), $\log E = X\lambda$, where E is the vector of model frequencies, X is the indicator matrix that contains the effects that define the base model, and λ is a parameter vector.

To give an example of a base model, consider the data in Table 1. In tables of this sort, researchers rarely need to ask the question whether an association between the earlier and the later observations exists. The X^2 -analysis confirms what everybody either knows or assumes: there is a strong association. It is, therefore, the goal of CFA to explore the cross-classification, and to identify those cells that deviate from the assumption of independence. These cells not only carry the association, they also define the developmental process that the researchers attempt to capture in this study. Later in this entry, we present a complete CFA of this table. In brief the main effects **log-linear model** of variable independence can be a CFA base model.

Another example of a log-linear CFA base model is that of Prediction CFA (P-CFA). This variant of CFA is used to identify patterns of predictor categories that go hand-in-hand with patterns of criteria categories. For example, one can ask whether particular patterns of categories that describe how students do (or do not do) their homework allow one to predict particular patterns of categories that describe the students' success in academic subjects. In this situation, the researchers are not interested in the associations among the predictors, and they are not interested in the associations among the criterion variables. Therefore, all these associations are part of the base model. It is saturated in the predictors, and it is saturated in the criteria. However, the researchers are interested in predictor-criterion relationships. Therefore, the base model proposes that the predictors are unrelated to the criteria. P-CFA types and antitypes indicate where this assumption is violated. P-CFA types describe where criterion patterns can be predicted from predictor patterns. P-CFA antitypes describe which criterion patterns do not follow particular predictor patterns.

A second group of base models uses prior information to determine the expected cell frequencies. Examples of prior information include population parameters, theoretical probabilities that are known, for instance, in coin toss or roulette experiments, or probabilities of transition patterns (see [16], Chapter 8).

A third group of base models determines expected cell frequencies based on distributional assumptions. For example, von Eye and Bogat [20] proposed estimating the expected cell probabilities based on the assumption that the categorized variables that span a cross-classification follow a multinormal distribution. CFA tests can then be used to identify those sectors that deviate from multinormality most strongly.

The first group of base models is log-linear. The latter two are not log-linear, thus illustrating the flexibility of CFA as a method of analysis of cross-classifications.

Sampling Schemes and Their Relation to CFA Base Models. When selecting a base model for CFA, first, the variable relationships the researchers are (not) interested in must be considered. This issue was discussed above. Second, the sampling scheme must be taken into account. The sampling scheme determines whether a base model is admissible (see **Sampling Issues in Categorical Data**). In the simplest case, sampling is multinomial (see **Catalogue of Probability Density Functions**), that is, cases are randomly assigned to all cells of the cross-classification. Multinomial sampling is typical in observational studies. There are no constraints concerning the univariate or multivariate marginal frequencies.

However, researchers determine marginal frequencies often before data collection. For example, in a comparison of smokers with nonsmokers, a study may sample 100 smokers and 100 nonsmokers. Thus, there are constraints on the marginals. If 100 smokers are in the sample, smokers are no longer recruited, and the sample of nonsmokers is completed. In this design, cases are no longer randomly assigned to the cells of the entire table. Rather, the smokers are randomly assigned to the cells for smokers, and the nonsmokers are assigned to the cells for nonsmokers. This sampling scheme is called *product-multinomial*. In univariate, product-multinomial sampling, the constraints are on the marginals of one variable. In multivariate, product-multinomial sampling, the constraints are on the marginals of multiple variables, and also on the cross-classifications of these variables. For example, the researchers of the smoker study may wish to include in their sample 50 female smokers from the age bracket between 20 and 30, 50 male smokers from the same age bracket, and so forth.

In log-linear modeling, the sampling scheme is of lesser concern, because it has no effect on the estimated parameters. In contrast, from the perspective of specifying a base model for CFA, taking the sampling scheme into account is of particular importance. In multinomial sampling, there are no constraints on the marginal probabilities. Therefore, any base model can be considered, as long as the estimated expected cell frequencies sum to equal the sample size. In contrast, if one or more variables are observed under a product-multinomial sampling scheme, constraints are placed on their marginal probabilities, and the marginal frequencies of these variables must be reproduced. This can be guaranteed by base models that include the main effects (and the interactions) of the (multiple) variables observed under the product-multinomial sampling scheme [16, 2003].

Concepts of Deviation from Independence

CFA types and antitypes result when the discrepancies between observed and expected frequencies are large. It is interesting to see that several definitions of such discrepancies exist [6]. Two of these definitions have been discussed in the context of CFA [22]. The definition that is used in the vast majority of applications of log-linear modeling and CFA is that of the *marginal-free* residual. This definition implies that the marginal probabilities are taken into account when the discrepancy between the observed and the expected cell probabilities is evaluated. For example, the routine standardized residual, $r_i = (m_i - e_i)/\sqrt{e_i}$, its equivalent $X^2 = r_i^2$, and the correlation ρ are marginal-dependent, and so is Goodman's [6] weighted log-linear interaction, which can be interpreted as the log-linear interaction, λ , with the marginal probabilities as weights. The second definition leads to measures that are *marginal-dependent*. This definition implies that the marginal probabilities have an effect on the magnitude of the measure that describes the discrepancy between the observed and the expected cell frequencies. Sample measures that are marginal-dependent are the log-linear interaction, λ , and the **odds ratio**, θ (see [21]). Von Eye et al. [22] showed that the pattern of types and antitypes that CFA can unearth can vary depending on whether marginal-free or marginal-dependent definitions of deviation from independence are used.

Selection of a Significance Test

Significance tests for CFA can be selected based on the following five characteristics:

- (1) *exact* versus *approximative* tests (see **Exact Methods for Categorical Data**); the **binomial test** is the most frequently used exact test;
- (2) statistical **power** [18, 23]; Lehman's [12] approximative hypergeometric test has the most power;
- (3) differential sensitivity of test to types and antitypes; most tests are more sensitive to types when samples are small, and more sensitive to antitypes when samples are large;
- (4) *sampling scheme*; any of the tests proposed for CFA can be used when sampling is multinomial; however, the exact and the approximative hypergeometric (see **Catalogue of Probability Density Functions**) tests (e.g., [12]) require product-multinomial sampling.
- (5) use for *inferential* or *descriptive* purposes; typically, tests are used for inferential purposes; odds ratios and correlations are often also used for descriptive purposes.

The following three examples of tests used in CFA illustrate the above characteristics. We discuss the binomial test, the Pearson X^2 component test, and Lehman's [12] approximative hypergeometric test. Let m_i denote the frequency that was observed for Cell i , and e_i the estimated expected cell frequency. Then, the Pearson X^2 test statistic is

$$X_i^2 = \frac{(m_i - e_i)^2}{e_i}. \quad (1)$$

This statistic is approximately distributed as χ^2 , with $df = 1$. For the binomial test, let the estimate of the probability of Cell i be $p_i = e_i/N$. The tail probability for m_i is then

$$b_i = \sum_{l=m_i}^N \binom{N}{l} p_i^l (1 - p_i)^{N-l} \quad (2)$$

For a CFA test of the form used for the Pearson component test, Lehman [12] derived the exact variance,

$$\sigma_i^2 = N p_i [1 - p_i - (N - 1)(p_i - \tilde{p}_i)], \quad (3)$$

4 Configural Frequency Analysis

where p_i is defined as for the binomial test, and

$$\tilde{p}_i = \frac{\prod_{j=1}^d (N_j - 1)}{(N - 1)^d}, \quad (4)$$

is where d is the number of variables that span the cross-classification, and j indexes these variables. Using the exact variance, the Lehmacher cell-specific test statistic can be defined as

$$z_i^L = \frac{m_i - e_i}{\sigma_i}. \quad (5)$$

Lehmacher's z is, for large samples, standard normally distributed. A continuity correction has been proposed that prevents Lehmacher's test from being nonconservative in small samples. The correction requires subtracting 0.5 from the numerator if $m > e$, and adding 0.5 to the numerator if $m < e$.

These three test statistics have the following characteristics:

- (1) The *Pearson X^2 component test* is an approximative test with average power. It is more sensitive to types when samples are small, and more sensitive to antitypes when samples are large. It can be applied under any sampling scheme, and is mostly used for inferential purposes.
- (2) The *binomial test* is exact, and can be used under any sampling scheme.
- (3) *Lehmacher's test* is approximative. It has the most power of all tests that have been proposed for use in CFA. It is more sensitive to types when samples are small, and more sensitive to antitypes when samples are large. The only exceptions are **2 × 2 tables**, where Lehmacher's test always identifies exactly the same number of types and antitypes. The test requires that the sampling scheme be product-multinomial, and can be used only when the CFA base model is the log-linear main effect model.

Protection of the Significance Threshold α

Typically, CFA applications are exploratory and examine all cells of a cross-classification. This strategy implies that the number of tests performed on the same data set can be large. If the number of tests is large, the α -level needs to be protected for two reasons (see **Multiple Comparison Procedures**). First,

there is *capitalizing on chance*. If the significance threshold is α , then researchers take the risk of committing an α -error at each occasion a test is performed. When multiple tests are performed, the risk of α comes with each test. In addition, there is a risk that the α -error is committed twice, three times, or, in the extreme case, each time a test is performed.

The second reason is that the tests in a CFA are dependent. Von Weber, Lautsch, and von Eye [23] showed that the results of three of the four tests that CFA can possibly perform in a 2×2 table are completely dependent on the results of the first test. In larger tables, the results of each cell-specific test are also dependent on the results of the tests performed before, but to a lesser extent. In either case, the α -level needs to be protected for the CFA tests to be valid.

A number of methods for α -protection has been proposed. The most popular and simplest method, termed *Bonferroni adjustment* (see **Multiple Comparison Procedures**), yields an adjusted significance level, α^* , that (a) is the same for each test, and (b) takes the total number of tests into account. The protected α -level is $\alpha^* = \alpha/c$, where c is the total number of tests performed. For example, let a cross-classification have $2 \times 3 \times 3 \times 2 = 36$ cells. For this table, one obtains the Bonferroni-protected $\alpha^* = 0.0014$. Obviously, this new, protected threshold is extreme, and it will be hard to find types and antitypes.

Therefore, less radical procedures for α protection have been devised. An example of these is Holm's [9] procedure. This approach takes into account (1) the maximum number of tests to be performed, and (2) the number of tests already performed before test i . In contrast to the Bonferroni procedure, the protected significance threshold α_i^* is not constant. Specifically, the Holm procedure yields the protected significance level

$$\alpha_i^* = \frac{\alpha}{c - i + 1}, \quad (6)$$

where i indexes the i th test that is performed. Before applying Holm's procedure, the test statistics have to be rank-ordered such that the most extreme statistic is examined first. Consider the first test; for this test, the Holm-protected α is $\alpha^* = \alpha/(c - 1 + 1) = \alpha/c$. This threshold is identical to the one used for the first test under the Bonferroni procedure. However, for the second test under Holm, we obtain $\alpha^* = \alpha/(c - 1)$, a

threshold that is less extreme and prohibitive than the one used under Bonferroni. For the last cell in the rank order, we obtain $\alpha^* = \alpha/(c - c + 1) = \alpha$. Testing under the Holm procedure concludes after the first null hypothesis prevails. More advanced methods of α -protection have been proposed, for instance, by Keselman, Cribbie, and Holland [10].

Identification and Interpretation of Types and Antitypes

Performing CFA tests usually leads to the identification of a number of configurations (cells) as constituting types or antitypes. The interpretation of these types and antitypes uses two types of information. First, types and antitypes are interpreted based on the *meaning of the configuration* itself. Consider, for example, the data in Table 1. Suppose Configuration 2-3 constitutes a type (below, we will perform a CFA on these data to determine whether this configuration indeed constitutes a type). This configuration describes those adolescents who develop from a Tanner stage 2 to a Tanner stage 3. That is, these adolescents make progress in their physical pubertal development. They are neither prepubertal nor physically mature, but they develop in the direction of becoming mature. Descriptions of this kind indicate the meaning of a type or antitype.

The second source of information is included in the decisions as they were processed in the five steps of CFA. Most important is the definition of the base model. If the base model suggests variable independence, as it does in the log-linear main effect base model, types and antitypes suggest local associations. If the base model is that of prediction CFA, types and antitypes indicate pattern-specific relationships between predictors and criteria. If the base model is that of two-group comparison, types indicate the patterns in which the two groups differ significantly.

The characteristics of the measure used for the detection of types and antitypes must also be considered. Measures that are marginal-free can lead to different harvests of types and antitypes than measures that are marginal-dependent.

Finally, the **external validity** of types and antitypes needs to be established. Researchers ask whether the types and antitypes that stand out in the space of the variables that span the cross-classification under study do also stand out, or

can be discriminated in the space of variables not used in the CFA that yielded them. For example, Görtelmeyer [7] used CFA to identify six types of sleep problems. To establish external validity, the author used ANOVA methods to test hypotheses about mean differences between these types in the space of personality variables.

Data Examples

This section presents two data examples.

Data example 1: Physical pubertal development.

The first example is a CFA of the data in Table 1. This table shows the cross-tabulation of two ratings of physical pubertal development in a sample of 64 adolescents. The second ratings were obtained two years after the first. We analyze these data using first order CFA. The base model of first order CFA states that the two sets of ratings are independent of each other. If types and antitypes emerge, we can interpret them as indicators of local associations or, from a substantive perspective, as transition patterns that occur more often or less often than expected based on chance.

To search for the types, we use Lehmacher's test with continuity correction and Holm's procedure of α -protection. Table 2 presents the results of CFA.

The overall Pearson X^2 for this table is 24.10 ($df = 4$; $p < 0.01$), indicating that there is an association between the two consecutive observations of physical pubertal development. Using CFA, we now ask whether there are particular transition patterns that stand out. Table 2 shows that three types and two antitypes emerged. Reading from the top of the table, the first type is constituted by Configuration 2-3. This configuration describes adolescents who develop from an early adolescent pubertal stage to a late adolescent pubertal stage. Slightly over nine cases had been expected to show this pattern, but 17 were found, a significant difference. The first antitype is constituted by Configuration 2-4. Fifteen adolescents developed so rapidly that they leaped one stage in the one-year interval between the observations, and showed the physical development of a mature person. However, over 24 had been expected to show this development. From this first type and this first antitype, we conclude that the development by one stage is normative, and the development by more

6 Configural Frequency Analysis

44	13	8.94	2.369	.0089	.01	T

^a $<\alpha^*$ indicates that the first four decimals are zero.

than one stage can be observed, but less often than chance.

If development by one stage is normative, the second transition from a lower to a higher stage in Table 2, that is, the transition described by Configuration 3-4, may also constitute a type. The table shows that this configuration also contains significantly more cases than expected.

Table 2 contains one more antitype. It is constituted by Configuration 3-3. This antitype suggests that it is very unlikely that an adolescent who has reached the third stage of physical development will still be at this stage two years later. This lack of stability, however, applies only to the stages of development that adolescents go through before they reach the mature physical stage. Once they reach this stage, development is completed, and stability is observed. Accordingly, Configuration 4-4 constitutes a type.

Data example 2. The second data example presents a reanalysis of a data set published by [4]. A total of 181 high school students processed the 24 items of a cube comparison task. The items assess the students' spatial abilities. After the cube task, the students answered questions concerning the strategies they had used to solve the task. Three strategies were used in particular: mental rotation (R), pattern comparison (P), and change of viewpoint (V). Each strategy was scored as either 1 = not used, or 2 = used. In the following sample analysis, we ask whether there are gender differences in strategy use. Gender was scaled as 1 = females and 2 = males. The analyses are performed at the level of individual responses.

The base model for the following analyses (1) is saturated in the three strategy variables that are used to distinguish the two gender groups, and (2) assumes that there is no relationship between gender and strategies used. If discrimination types emerge, they indicate the strategy patterns in the two gender groups differ significantly. For the analyses, we use Pearson's X^2 -test, and the Bonferroni-adjusted $\alpha^* = .05/8 = 0.00625$. Please note that the numerator for the calculation of the adjusted α is 8 instead of 16, because, to compare the gender groups, one test is performed for each strategy pattern (instead of two, as would be done in a one-sample CFA). Table 3 displays the results of 2-group CFA.

The results in Table 3 suggest strong gender differences. The first discrimination type is constituted by Configuration 111. Twenty-five females and five males used none of the three strategies. This difference is significant. The second discrimination type is constituted by Configuration 122. Thirteen males and 63 females used the pattern comparison and the viewpoint change strategies. Discrimination type 221 suggests that the rotational and the pattern comparison strategies were used by females in 590 instances, and by males in 872 instances. The last discrimination type emerged for Configuration 222. Females used all three strategies in 39 instances; males used all three strategies in 199 instances.

We conclude that female high school students differ from male high school students in that they either use no strategy at all, or use two. If they use two strategies, the pattern comparison strategy is one of them. In contrast, male students use all

Table 3 Two-group CFA of the cross-classification of rotation strategy (R), pattern comparison strategy (P), viewpoint strategy (V), and gender (G)

Configuration	m	e	statistic	p	Type?

three strategies significantly more often than female students.

Summary and Conclusions

CFA has found applications in many areas of the social sciences, recently, for instance, in research on child development [1, 14], and educational psychology [15]. Earlier applications include analyses of the control beliefs of alcoholics [11]. CFA is the method of choice if researchers test hypotheses concerning *local associations* [8], that is, associations that hold in particular sectors of a cross-classification only. These hypotheses are hard or impossible to test using other methods of categorical data analysis.

Software for CFA can be obtained free from von-eye@msu.edu. CFA is also a module of the software package SLEIPNER, which can be downloaded, also free, from <http://www.psychology.su.se/sleipner/>.

Confounding in the Analysis of Variance

Unintentional Confounding

In the analysis of variance (ANOVA), we usually study the effects of categorical independent variables on a numerical-valued dependent variable. Two independent variables are confounded if one is *found with* the other and the two as they stand are inseparable. This means that each time one variable has a given value, the other variable has a matched value. As a consequence, we lose the ability to estimate separately the effects of these two variables or the interaction of these variables with other variables. Conclusions as to which variable had an effect become impossible without making some additional assumption or taking some additional measure.

Consider visual habituation in infants. With repeated presentations of a visual stimulus, infants eventually look at it less and less. The standard interpretation is that the infant forms a representation of the stimulus and that looking decreases as the representation requires less and less correction from the visual input. But habituation requires time in the experiment. So, the number of habituation trials is confounded with time in the experiment. How do we know that the diminished looking is not due to fatigue that might naturally increase with more time in the experiment? One standard tactic is to present a novel stimulus at the conclusion of the habituation trials. Renewed looking to the novel stimulus accompanied by decreased looking to the familiar one argues against fatigue and in favor of the habituation process.

In between-subject designs, we obtain a single measure from a subject. In repeated measures designs (see **Repeated Measures Analysis of Variance; Longitudinal Data Analysis**), we measure the subject repeatedly. Each approach carries its own dangers of confounding and its own methods of remedy.

Between-subjects Designs

Either we run all the subjects at once or some subjects are run before others, either individually or in batches. Almost always, running individual subjects is preferable. With running subjects individually or

in batches, order effects may be confounded with the treatment effects. Drift or refinement in the experimental procedure, change of experimenter, of season, and so on, all may be confounded with the treatment effects. Protection from such confounding can be achieved by randomly assigning the subjects to the conditions and by randomly assigning the order of running the subjects (see **Randomization**). The subjects are still confounded with the experimental conditions since each experimental condition entails scores from some subjects and not from others. The random assignment of subjects to conditions protects against but does not remove such confounding.

Repeated Measures Designs

Different risks of confounding occur in repeated measures designs. A subject is measured on each of a series of occasions or trials. Ideally, to compare the effects of one treatment versus another we would like the subject to be identical on each occasion. But if a subject has been subjected to an earlier treatment, there is always the possibility that a residual effect of the earlier treatment remains at the time of the later one. Thus, the residual effect of the earlier treatment may not be separable from the effect of the later treatment.

Sometimes, it is that very accumulation of effect that is the object of study as in the habituation example. In such cases, the inseparability of the effect of a particular occasion from the accumulation of previous effects ordinarily is not a problem and we do not speak of confounding. Such separation as can be accomplished is usually in terms of a mathematical model of the process that assigns an effect of a given occasion in terms of the present event and the previous effects. Clarification of the separate effects then becomes a matter of the **goodness of fit** of the model.

On the other hand, often there are risks of cumulative effects that are both unintended and undesirable. The amount of time in the experiment can produce trial-to-trial effects such as warm-up, fatigue, and increased sensitivity to distraction. Also, amount of time can result in improved skill at performing the task with a consequent freeing up of mental processing space so that the subject on later trials has more freedom to devote to formulating conjectures about the purpose of the experiment, the motivation of the

2 Confounding in the Analysis of Variance

experimenter, and so on, which in turn may affect performance.

Another form of confounding comes not from a progressive buildup over trials but simply from the carryover of the effect of one trial to the response on the next. We can imagine an experiment on taste sensitivity in which the subject repeatedly tastes various substances. Obviously, it is important to remove traces of the previous taste experience before presenting the next one.

Mixed Designs

Mixed designs combine the features of between-subject designs with those of repeated measures designs (*see Fixed and Random Effects*). Different sets of subjects are given the repeated measures treatments with one and only one value of a between-subjects variable or one combination of between-subject variables. In this type of design, both types of confounding described above can occur. The between-subject variables can be confounded with groups of subjects and the within-subject variables can be confounded with trial-to-trial effects.

Intentional Planned Confounding or Aliasing

If when variables are confounded we cannot separate their effects, it may be surprising that we would ever intentionally confound two or more variables. And yet, there are circumstances when such confounding can be advantageous. In general, we do so when we judge the gains to exceed the losses. Research has costs. The costs involve resources such as time, money, lab space, the other experiments that might have been done instead, and so on. The gains from an experiment are in terms of information about the way the world is and consequent indications of fruitful directions for more research. Every experiment is a trade-off of resources against information.

Intentional confounding saves resources at the cost of information. When the information about some variable or interaction of variables is judged to be not worth the resources it takes to gain the information, confounding becomes a reasonable choice. In some cases, the loss of information is free of cost if we have no interest in that information. We have already seen an example of this in the case of between-subject

designs where subjects are confounded with treatment conditions. We have elected to ignore information about individual subjects in favor of focusing on the treatment effects.

In a design, there are groups of subjects, there are treatments, and there are interactions. Any two of these can be confounded with each other. So, for example, we have the split-plot design in which groups are confounded with treatments, the confounded factorial designs in which groups are confounded with **interactions**, and the fractional replication designs in which treatments are confounded with interactions (*see Balanced Incomplete Block Designs*). In the case of the latter two designs, there may be interactions that are unimportant or in which we have no interest. We can sometimes cut the cost of running subjects in half by confounding such an interaction with groups or with treatments. Kirk [3] provides an extensive treatment of designs with confounding. The classic text by Cochran and Cox [2] is also still an excellent resource.

An Example of Intentional Confounding

An example of confounding groups of subjects with a treatment effect can be seen in the following experimental design for studying an infant looking in response to possible and impossible arithmetic manipulations of objects [1]. Two groups of infants are given four trials in the following situation: An infant is seated in front of a stage on which there are two lowered screens, one on the left, the other on the right. When the screen is lowered, the infant can see what is behind it, and when the screen is raised the infant cannot see. An object is placed behind the lowered left screen, the screen is raised, either one or two additional objects are placed behind the raised left screen, an object is placed behind the lowered right screen, the screen is raised, either one or two additional objects are placed behind the raised right screen. Thus, each screen conceals either two or three objects. One of the two screens is then lowered and either two or three objects are revealed. The duration of the infant looking at the revealed objects is the basic measure. The trials are categorized as possible or impossible, revealing two or three objects, and involving a primacy or recency effect. On possible trials, the same number hidden behind the screen is revealed; on impossible, a different

number is revealed. Primacy refers to revealing what was behind the left screen since it was hidden first; recency refers to revealing the more recently hidden objects behind the right screen. Number revealed of course refers to revealing two or revealing three objects. Thus, with two objects hidden behind the left screen and three objects finally revealed behind the left screen, we have a combination of the three, impossible, and primacy effects. A complete design would require eight trials for each infant: a $2 \times 2 \times 2$ factorial design of number $\times$ possibility $\times$ recency. Suppose previous experience indicates that the full eight trials would probably result in declining performance with 10-month-old infants. So the design in Table 1 is used:

Inspection of the table shows that the primacy effect is perfectly confounded with the possibility $\times$ number revealed $\times$ group interaction. In the present context, a primacy effect seems reasonable in that the infants might have difficulty remembering what was placed behind the first screen after being exposed to the activity at the second screen. On the other

hand, it seems unlikely that a possibility $\times$ number revealed $\times$ group interaction would exist, especially since infants are assigned to groups at random and the order of running infants from the different groups is randomized. In this context, a significant group $\times$ possibility $\times$ number interaction is reasonably interpreted as a recency effect.

The design described above contains a second confound. Primacy-recency is confounded with spatial location of the screen (left or right). The first concealment was always behind the left screen; the second, always behind the right. This means that preferring to look longer to the right than to the left would result in an apparent recency preference that was in fact a position preference. If such a position preference were of concern, the design would have to be elaborated to include primacy on the left for some infants and on the right for others.

Confounding Variable

Consider testing a causal model with an explanatory variable A and a response variable B . In testing such a causal model, a confounding variable C is a variable that is related to the explanatory variable A and at the same time has an effect on the response variable B that is mixed up with the effect of the explanatory variable A [3]. The existence of this confounding variable makes it difficult to assess the size of the effect of the explanatory variable or sometimes even calls the causal link between the explanatory variable and the response variable into question. Confounding variables are able to inflate as well as shrink the observed covariation (*see Covariance/variance/correlation*) between explanatory and response variables, and in some cases, the confounding variable can be held responsible for all of the observed covariation between the explanatory and the response variable (cases of so-called spurious correlation, [1]). Reasons for confounding can be found in the type of research that is being conducted – and that can make it difficult to avoid confounding – or in unanticipated systematic errors in experimental design.

For example, in school effectiveness research, one is interested in the effect of schools and educational practices (A) on student achievement (B). In one Belgian study, 6411 pupils entering one of 57 schools were followed during their secondary schooling career (between ages 12 and 18 yr) using questionnaires related to their language achievement, mathematical skills, attitudes, well-being, and other psychosocial variables [6]. If one wants to establish a causal link between the (type of) school the pupil is attending (A) and his later achievement (B), then student achievement on entrance of the school (C) is an obvious confounding variable. C is related to A because students are not randomly assigned to schools (some schools attract higher-achieving students than others) and at the same time C has a strong link to B because of the relative stability of student achievement during secondary education [6]. It is therefore likely that at least a part of the relation between the school (A) and the later achievement (B) is explained by the initial achievement (C) rather than to a causal relationship between A and B .

Of course, confounding can also be due to more than one variable and can also occur when more complex causal models are considered. In an observational study, like the school effectiveness study just mentioned, a large number of confounding variables could be present. Besides prior achievement, also socioeconomic background, ethnicity, motivation, intelligence, and so on, are potential confounding variables, which would have to be checked before any causal claim can reasonably be made [6].

Although confounding is most evident in the context of **observational studies** and **quasi-experiments** [4, 5], also in randomized experiments one has to be careful for unexpected confounding variables. A striking example can be found in the infamous Pepsi versus Coca-Cola taste comparisons. Alleged Coca-Cola drinkers were given the blind choice between a glass marked Q (containing Coca-Cola) and a glass marked M (containing Pepsi). Much to the surprise of the Coca-Cola officials, significantly more tasters preferred the glass containing Pepsi. However, in a control test it was found that blind tasters preferred the glass marked M even if both glasses contained Coca-Cola. Apparently, in the first study, letters were a confounding variable. People seem to have a preference for high-frequent letters, implying a preference for the drink that was (accidentally?) associated with the most frequent letter [2].

Confounding variables are detrimental to the **internal validity** of any empirical study, and much of the current work on observational and quasi-experimental research deals with methods to avoid or to rule out confounding variables, or to model them as covariates. Excellent technical accounts can be found in [4] and [5].

Contingency Tables

Contingency tables result from cross-classifying a sample from some population with respect to two or more qualitative (categorical) variables. The cells of such tables contain frequency counts of outcomes. Contingency tables are very common in many areas, for example, all branches of epidemiology, medicine, in particular, psychiatry, and in the social sciences, and psychology. Examples of various types of contingency tables are shown in Tables 1, 2, and 3.

The data in Table 1 come from [6], and arise from classifying 21 accounts of threatened suicide by jumping from high structures, according to the time of year and whether jeering or baiting behavior occurred amongst the onlookers. Interest lies in the question of whether baiting is more likely to occur in warm weather (the data come from the northern hemisphere, so June to September are the warm months).

Table 2 is taken from the 1991 General Social Survey and is also reported in [1]. Here, race and party identification are cross classified.

Table 3 is reported in [5], and involves data from a study of seriously emotionally disturbed (SED) and learning disabled (LD) adolescents.

Tables 1 and 2 are examples of *two-dimensional contingency tables*, that is, data cross-classified with respect to two categorical variables, and Table 3 is a *four-way contingency table*. Table 1, in which each variable has two categories, is also generally known as a **two-by-two contingency table**.

Table 1 Crowds and threatened suicide

Period	Crowd	
	Baiting	Nonbaiting
July – September	8 (<i>a</i>)	4 (<i>b</i>)
October – May	2 (<i>c</i>)	7 (<i>d</i>)

Table 2 Party identification and race (from the 1991 General Social Survey)

Race	Party identification		
	Democrat	Independent	Republican
White	341	105	405
Black	103	15	11

Table 3 Depression in adolescents

Age	Group	Sex	Depression	
			Low	High
12–14	LD	Male	79	18
		Female	34	14
	SED	Male	14	5
		Female	5	8
15–16	LD	Male	63	10
		Female	26	11
	SED	Male	32	3
		Female	15	7
17–18	LD	Male	36	13
		Female	16	1
	SED	Male	36	5
		Female	12	2

SED: Seriously emotionally disturbed. LD: Learning disabled.

Testing for Independence in Two-dimensional Contingency Tables

The hypothesis of primary interest for two-dimensional contingency tables is whether the two variables involved are independent. This may be formulated more formally in terms of p_{ij} , the probability of an observation being in the ij th cell of the table, $p_{i.}$, the probability being in the i th row of the table, and $p_{.j}$, the probability being in the j th column of the table. The null hypothesis of independence can now be written:

$$H_0: p_{ij} = p_{i.} \times p_{.j} \quad (1)$$

Estimated values of $p_{i.}$ and $p_{.j}$ can be found from the relevant marginal totals ($n_{i.}$ and $n_{.j}$) and overall sample size (N) as

$$\hat{p}_{i.} = \frac{n_{i.}}{N}, \hat{p}_{.j} = \frac{n_{.j}}{N} \quad (2)$$

and these can then be combined to give the estimated probability of being in the ij th cell of the table under the hypothesis of independence, namely, $\hat{p}_{i.} \times \hat{p}_{.j}$. The frequencies to be expected under independence, E_{ij} , can then be obtained simply as

$$E_{ij} = N \times \hat{p}_{i.} \times \hat{p}_{.j} = \frac{n_{i.} \times n_{.j}}{N} \quad (3)$$

Independence can now be assessed by comparing the observed (O_{ij}) and estimated expected frequencies

2 Contingency Tables

(E_{ij}) using the familiar test statistic;

$$X^2 = \sum_{i=1}^r \sum_{j=1}^c \frac{(O_{ij} - E_{ij})^2}{E_{ij}} \quad (4)$$

where r is the number of rows and c the number of columns in the table. Under H_0 , the distribution of X^2 is, for large N , approximately a *chi-squared distribution* (see **Catalogue of Probability Density Functions**) with $(r-1)(c-1)$ degrees of freedom. Hence, for a significance test of H_0 with approximate significance level α , we reject H_0 if

$$X^2 \geq \chi^2(\alpha)_{(r-1)(c-1)} \quad (5)$$

where $\chi^2(\alpha)_{(r-1)(c-1)}$ is the upper α point of a chi-squared distribution with $(r-1)(c-1)$ degrees of freedom.

In the case of a two-by-two contingency table with cell frequencies a, b, c , and d , (see Table 1), the X^2 statistic can be written more simply as

$$X^2 = \frac{N(ad - bc)^2}{(a+b)(c+d)(a+c)(b+d)} \quad (6)$$

And in such tables, the independence hypothesis is equivalent to that of the equality of two probabilities, for example, in Table 1, that the probability of crowd baiting in June–September is the same as the probability of crowd baiting in October–May.

Applying the chi-squared test of independence to Table 2 results in a test statistic of 79.43 with two degrees of freedom. The associated P value is very small, and we can conclude with some confidence that party identification and race are not independent. We shall return for a more detailed look at this result later.

For the data in Table 1, the chi-square test gives $X^2 = 4.07$ with a single degree of freedom and a P value of 0.04. This suggests some weak evidence for a difference in the probability of baiting in the different times of the year. But the frequencies in Table 1 are small, and we need to consider how this might affect an asymptotic test statistic such as X^2 .

Small Expected Frequencies

The derivation of the chi-square distribution as an approximation for the distribution of the X^2 statistic is made under the rather vague assumption that the expected values are not ‘too small’. This has, for

many years, been interpreted as implying that all the expected values in the table should be greater than five for the chi-square test to be strictly valid. Since in Table 1 the four expected values are 5.7, 6.2, 4.3, and 4.7, this would appear to shed some doubt on the validity of the chi-squared test for the data and on the conclusion from this test. But as long ago as 1954, Cochran [3] pointed out that such a ‘rule’ is too stringent and suggested that if relatively few expected values are less than five (say one cell in five), a minimum value of one is allowable.

Nevertheless, for small, sparse data sets, the asymptotic inference from the chi-squared test may not be valid, although it is usually difficult to identify *a priori* whether a given data set is likely to give misleading results. This has led to suggestions for alternative test statistics that attempt to make the asymptotic P value more accurate. The best known of these is **Yates’ correction**. But, nowadays, such procedures are largely redundant since *exact* P values can be calculated to assess the hypothesis of independence; for details, see the **exact methods for categorical data** entry.

The availability of such ‘exact methods’ also makes the pooling of categories in contingency tables to increase the frequency in particular cells, unnecessary. The procedure has been used almost routinely in the past, but can be criticized on a number of grounds.

- A considerable amount of information may be lost by the combination of categories, and this may detract greatly from the interest and usefulness of the study.
- The randomness of the sample may be affected; the whole rationale of the chi-squared test rests on the randomness of the sample and in the categories into which the observations may fall being chosen in advance.
- Pooling categories after the data are seen may affect the random nature of the sample with unknown consequences.
- The manner in which categories are pooled can have an effect on the resulting inferences.

As an example, consider the data in Table 4 from [2]. When this table is tested for independence using the chi-squared test, the calculated significance level is 0.086, which agrees with the exact probability

Table 4 Hypothetical data from Baglivo [2]

	Column				
	1	2	3	4	5
Row 1	2	3	4	8	9
Row 2	0	0	11	10	11

to two significant figures, although a standard statistical package issues a warning of the form ‘some of the expected values are less than two, the test may not be appropriate’. If the first two columns of Table 4 are ignored, the P value becomes 0.48, and if the first two columns are combined with the third, the P value becomes one.

The practice of combining categories to increase cell size should be avoided and is nowadays unnecessary.

Residuals

In trying to identify which cells of a contingency table are primarily responsible for a significant overall chi-squared value, it is often useful to look at the differences between the observed values and those values expected under the hypothesis of independence, or some function of these differences. In fact, looking at **residuals** defined as observed value – expected value would be very unsatisfactory since a difference of fixed size is clearly more important for smaller samples. A more appropriate residual would be r_{ij} , given by:

$$r_{ij} = \frac{(n_{ij} - E_{ij})}{\sqrt{E_{ij}}} \quad (7)$$

These terms are usually known as *standardized residuals* and are such that the chi-squared test statistic is given by

$$X^2 = \sum_{i=1}^r \sum_{j=1}^c r_{ij}^2 \quad (8)$$

It is tempting to think that the size of these residuals may be judged by comparison with standard normal percentage points (for example ± 1.96). Unfortunately, it can be shown that the variance of r_{ij} is always less than equal to one, and in some cases, the variance may be *considerably* less

than one. Consequently, the use of standardized residuals in the detailed examination of a contingency table may often give a conservative indication of a cell’s lack of fit to the independence hypothesis.

An improvement over standardized residuals is provided by the *adjusted residuals* (d_{ij}) suggested in [4], and defined as:

$$d_{ij} = \frac{r_{ij}}{\sqrt{[(1 - n_{i.}/N)(1 - n_{.j}/N)]}} \quad (9)$$

When the variables forming the contingency table are independent, the adjusted residuals are approximately normally distributed with mean zero and standard deviation one.

Returning to the data in Table 2, we can now calculate the expected values and then both the standardized and adjusted residuals – see Table 5. Clearly, the lack of independence of race and party identification arises from the excess of blacks who identify with being Democrat and the excess of whites who identify with being Republican.

Table 5 Expected values, standardized residuals, and adjusted residuals for data in Table 2

(1) Expected values

Race	Party identification		
	Democrat	Independent	Republican
White	385.56	104.20	361.24
Black	58.44	15.80	54.76

(2) Standardized residuals

Race	Party identification		
	Democrat	Independent	Republican
White	−2.27	0.08	2.30
Black	5.83	−0.20	−5.91

(3) Adjusted residuals

Race	Party identification		
	Democrat	Independent	Republican
White	−8.46	0.23	8.36
Black	8.46	−0.23	−8.36

In many cases, an informative way of inspecting residuals is to display them graphically using **correspondence analysis** (see **Configural Frequency Analysis**).

Higher-Dimensional Contingency Tables

Three- and higher-dimensional contingency tables arise when a sample of individuals is cross-classified with respect to three (or more) qualitative variables. A four-dimensional example appears in Table 3.

The analysis of such tables presents problems not encountered with two-dimensional tables, where a single question is of interest, namely, that of the independence or otherwise of the two variables involved. In the case of higher-dimensional tables, the investigator may wish to test that some variables are independent of some others, that a particular variable is independent of the remainder or some more complex hypothesis. Again, however, the chi-squared statistic is used to compare observed frequencies with estimates of those to be expected under a particular hypothesis.

The simplest question of interest in a three-dimensional table, for example, is that of the mutual independence of the three variables; this is directly analogous to the hypothesis of independence in a two-way table, and is tested in an essentially equivalent fashion. Other hypotheses that might be of interest are those of the partial independence of a pair of variables, and the conditional independence of two variables for a given level of the third. A more involved hypothesis is that the association between

two of the variables is identical in all levels of the third.

For some hypotheses, expected values can be obtained directly from simple calculations on particular marginal totals. But this is not always the case, and for some hypotheses, the corresponding expected values have to be estimated using some form of iterative procedure – for details see [1].

Three- and higher-dimensional contingency tables are best analyzed using **log-linear models**.

Coombs, Clyde Hamilton

Born: July 22, 1912, in New Jersey, USA.

Died: February 4, 1988, in Michigan, USA.

Clyde H. Coombs contributed to the development of modern **mathematical psychology**. His significance derived from a comprehensive vision of the place of mathematics in social and behavioral science, his ability to integrate diverse influences into that vision, and his willingness to locate novel applications of theoretical insights.

Coombs pioneered a radical approach to psychometrics. Initially struck by L.L. Thurstone's work, he came to believe that the traditional approach is based upon implausibly strong assumptions. His alternative was to derive quantitative conclusions from the qualitative structure of psychological data [1]. The best known example is his unfolding procedure, in which the underlying quantitative structure of a unidimensional stimulus set is (approximately) recovered from peoples' preferences, given the hypothesis of single-peaked preference functions. This hypothesis is that each person has a single point of maximum preference on the relevant dimension around which strength of preference decreases symmetrically. Thus, any person's preference ordering entails an ordering on differences. The idea of basing measurement upon qualitative relations between differences had been explored by mathematicians and economists, but was neglected in psychology. Coombs's original insight was to link this idea to individual differences in preference. Each person's preference ordering implies a distinct partial order on the set of interstimulus midpoints and since different people may have different points of maximum preference, the conjunction of these different partial orders implies an ordering upon the complete set of interstimulus distances.

The analogy between psychology and geometry is the heart of Coombs's general theory of data [2]. He represented wide classes of qualitative data by spatial structures. The combination of this analogy and the hypothesis of single-peaked preference functions gave Coombs a powerful analytical tool, applicable in areas as diverse as choices amongst gambles, political preferences, and conflict resolution. Coombs's thesis that qualitative data

may contain quantitative information proved enormously fruitful. Subsequent work in measurement theory (*see* **Measurement: Overview**), for example, the theories of **multidimensional scaling** and additive conjoint measurement, exploited the insight that qualitative data afford quantitative representations.

Coombs received his A.B. in 1935 and his M.A. in 1937 from the University of California, Berkeley. He then joined Thurstone at the University of Chicago, where he received his Ph.D. in 1940. For the next six years he worked as a research psychologist with the US War Department and subsequently moved to the Psychology Department at the University of Michigan in 1947. He remained at Michigan throughout his career, chairing its Mathematical Psychology Program. He spent visiting terms at the Laboratory of Social Relations at Harvard University, at the Center for Advanced Study in the Behavioral Sciences in Palo Alto, was a Fulbright Fellow at the University of Amsterdam, and following retirement, also taught at the Universities of Hamburg, Calgary, and Santa Barbara. He served as president of the Psychometric Society, was the first head of the Society for Mathematical Psychology, was an honorary fellow of the American Statistical Association, and was elected to the National Academy of Arts and Sciences and to the National Academy of Science.

Because of their fertility and generality, Coombs's contributions to mathematical psychology and psychological theory endure. However, equally important was his contribution to a fundamental change in attitude towards measurement. According to operationism, which had a profound impact upon psychology, measurement is prior to theory in science. According to Coombs, measurement is inextricably theoretical and, importantly, a measurement theory may be false, which means that 'not everything that one would like to measure is measurable' ([3], page 39).

Correlation

Correlation is a general term that describes whether two variables are associated [1–3]. The term associated means ‘go together’, that is, knowing the value of one variable, X , enables better prediction of a correlated (associated) variable, Y .

Correlation does *not* imply causality. Height and vocabulary of children are correlated – both increase with age. Clearly, an increase in height does not *cause* an increase in vocabulary, or vice versa. Other examples are less clear. Years of education and income are known to be correlated. Nevertheless, one cannot deduce that more education *causes* higher income. Correlations may be weak or strong, positive or negative, and linear or nonlinear.

Presentation

Correlation can best be seen by a **scatterplot** graph (Figure 1) showing Y as a function of X , together with

a line or curve representing the ‘best fitting’ relation between Y and X . ‘Best fitting’ means that the sum of some measure of deviation of all points from the line or curve is a minimum.

Linear or nonlinear? A linear correlation is one in which the relationship between variables is a straight line. Panels A–C show linear correlations. Panel D shows a nonlinear positive quadratic relation such as the famous Yerkes–Dodson law relating performance to arousal. Panel E shows a nonlinear negative exponential relation, such as the dark adaptation curve relating minimum light energy required to see as a function of time in the dark.

Weak or strong? A strong correlation occurs when knowing one variable strongly predicts the other variable. Panel B shows a weak positive correlation. Panel F shows no correlation for the bulk of points, the horizontal line of best fit; but a substantial correlation, the dashed diagonal line, when the single

Figure 1 Examples of possible associations between two variables X and Y

2 Correlation

outlier at (29,29) is included. All other panels show some strong relationship.

Positive or negative? Positive correlations arise when both variables increase together, like age and experience, as in Panels A and B. Negative correlations occur when one variable goes down as the other goes up, like age and strength in adults, as in Panel C.

Measures and Uses of Correlation

Measures of correlation range from $+1$, indicating perfect positive agreement to -1 , indicating perfect negative agreement. **Pearson's product moment correlation** r , can be used when both variables are metric (interval or ratio) (see **Scales of Measurement**) and normally distributed. Rank-based measures such as **Spearman's rho** r_s (Pearson's correlation of ranks) or **Kendall's tau** (a measure of how many transpositions are needed to get both variables in the same order) are also useful (sometimes known as nonparametric measures). They are applicable when either variable is ordinal, for example, ranking of candidates; or when metric data has **outliers** or is not bivariate normal. Experts [2] recommend τ over r_s ,

but r_s is widely used and easier to calculate. The **point biserial coefficient** is applicable if one variable is dichotomous and the other metric or ordinal.

Individual correlations are useful in their own right. In addition, correlation matrices, giving all the pairwise correlations of N variables, are useful as input to other procedures such as **Factor Analysis** and **Multidimensional Scaling**.

Correlation and Covariance Matrices

Covariance and correlation are measures of the degree to which the values on one variable are linearly related to the values on another. In that sense they measure the strength of directional association between two variables. For example, self-esteem is positively correlated with feelings of economic security and negatively correlated with feelings of social isolation [2].

An account of the early history of the term correlation is given in [4]. The term was used during the middle of the nineteenth century, but its statistical use is attributed to **Francis Galton**, who was interested in the relationships between characteristics of related individuals; for example, the correlation between children's and parents' height. The *correlation coefficient* as the central tool for the study of relationships between variables was further developed by F.Y. Edgeworth and **Karl Pearson**, who employed it to look at relationships between physiological and behavioral measurements on the same sets of people.

The population covariance is a measure of the extent to which two variables X and Y are linearly related. It is defined as the expectation (mean)

$$\sigma_{XY} = E[(X - E(X))(Y - E(Y))] \quad (1)$$

and it measures the association between X and Y because whenever a pair of values on X and Y are both above or both below their respective means they add to the covariance whereas if one is above and the other below they reduce it. When Y is a linear function of X (i.e., $Y = a + bX$ where b is a positive constant), then the covariance of X and Y is the product of the standard deviations of X and Y ($\sigma_X \sigma_Y = b \sigma_X^2$) and it is minus this value when $Y = a - bX$. Thus, the covariance ranges from $+\sigma_X \sigma_Y$ to $-\sigma_X \sigma_Y$ as the extent of the linear relationship goes from perfectly positive to perfectly negative.

A population correlation is defined to be the covariance divided by the product of the standard deviations $\sigma_X \sigma_Y$ and it ranges from 1 to -1 . This measure is sometimes called the **Pearson product-moment correlation** and it is useful because it does

not depend on the scale of X and Y assuming they are measured on interval scales. Another interpretation of a correlation is that its square is the proportion of the variance of any one of the variables that is explained in a linear regression (see **Multiple Linear Regression**) equation predicting it from the other variable. It should be remembered that when a correlation or covariance is zero, the variables are not necessarily independent. It only means that there is no linear relationship between the variables. Other nonlinear relationships, for example, a U-shaped relationship, may be present. More information about the interpretation of correlations can be found in [1].

The sample covariance is computed as

$$s_{xy} = \frac{1}{N-1} \sum_{i=1}^N (x_i - \bar{x})(y_i - \bar{y}), \quad (2)$$

where N is the sample size, $\bar{x}$ is the mean of the sample $x_1, \dots, x_N$, and $\bar{y}$ is the mean of $y_1, \dots, y_N$. As with the variance, the covariance when calculated from a sample is divided by the factor $N-1$ to provide an unbiased estimator of the population covariance. The **Pearson product-moment correlation coefficient** [3] can be used to estimate the population correlation and is calculated from the sample as

$$r_{xy} = \frac{\sum_{i=1}^N (x_i - \bar{x})(y_i - \bar{y})}{\left[\sum_{i=1}^N (x_i - \bar{x})^2 \sum_{i=1}^N (y_i - \bar{y})^2 \right]^{0.5}} \quad (3)$$

Figure 1 illustrates correlations of a number of different sizes where the only relationship between the variables is linear.

When covariances are used to characterize the relationships between a set of random variables $Z_1, \dots, Z_n$, they are typically presented in the form of a square and symmetric *variance-covariance matrix*

$$\Sigma = \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \dots & \sigma_{1n} \\ \sigma_{21} & \sigma_2^2 & \dots & \sigma_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{n1} & \sigma_{n2} & \dots & \sigma_n^2 \end{bmatrix} \quad (4)$$

where $\sigma_{ij} = \sigma_{ji}$ is the covariance between Z_i and Z_j and the diagonal elements are all equal to the

2 Correlation and Covariance Matrices

Figure 1 Scatter plots with regression lines illustrating Pearson correlations of 1.0, 0.8, 0.5, 0.2, 0, and -0.5 . X and Y are approximately normally distributed variables with means of 0 and standard deviations of 1

variances because the covariance of a variable with itself is its variance. When correlations are used they are presented in the form of a square correlation matrix

$$\Phi = \begin{bmatrix} 1 & \rho_{12} & \dots & \rho_{1n} \\ \rho_{21} & 1 & \dots & \rho_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{n1} & \rho_{n2} & \dots & 1 \end{bmatrix} \quad (5)$$

where ρ_{ij} is the correlation between Z_i and Z_j . The diagonal elements of the matrix are unity since by definition a variable can be fully predicted by itself. Also note that in the special case where variables are standardized to unit standard deviation the covariance matrix becomes the correlation matrix.

The variance-covariance matrix is important in multivariate modeling because relationships between variables are often taken to be linear and the multivariate **central limit theorem** suggests that a multivariate normal distribution (see **Catalogue of**

Probability Density Functions), which can be fully characterized by its means and covariance matrix, is a suitable assumption for many multivariate models (see **Multivariate Analysis: Overview**). For example, the commonly employed multivariate techniques **principal component analysis** and **factor analysis** operate on the basis of a covariance or correlation matrix, and the decision whether to start with the covariance or the correlation matrix is essentially one of choosing appropriate scales of measurement.

Correlation Issues in Genetics Research

Correlation is of central importance in behavioral genetic research. A basic goal of behavioral genetic research is to partition variance in a trait into variance due to genetic differences among people (commonly referred to as **heritability** (or h^2), variance because of environmental influences shared among family members (shared environmental variance, or c^2), and non-shared environmental variance as a result of unique individual experiences (e^2) (see **ACE Model**). This is accomplished by analyzing correlational structure within different familial relationships. Although in practice we perform **maximum-likelihood** model-fitting analyses on raw data and partition (unstandardized) covariance structure, examining familial correlations directly is the best way of quickly getting an idea of what is going on in the data.

There are two general classes of correlation to estimate the extent of similarity between two (or more) variables. The standard Pearson (interclass) correlation (see **Pearson Product Moment Correlation**) is appropriate when we have two variables measured on a set of individuals. For example, if we have a set of N people on whom we measure height (x) and weight (y), we can compute the interclass correlation between height and weight by first computing the sums of squares of x (SS_x) and y (SS_y) and the sum of cross products of x and y (SS_{xy}):

$$SS_x = \sum_{i=1}^N (x_i - \bar{x})^2 \quad (1)$$

$$SS_y = \sum_{i=1}^N (y_i - \bar{y})^2 \quad (2)$$

$$SS_{xy} = \sum_{i=1}^N (x_i - \bar{x})(y_i - \bar{y}) \quad (3)$$

where $\bar{x}$ and $\bar{y}$ are the mean of x and y , respectively. The **intraclass correlation**, r , is then given by:

$$r = \frac{SS_{xy}}{\sqrt{SS_x SS_y}} \quad (4)$$

In univariate behavioral genetic analyses, we deal with a single variable, for example, the personality trait neuroticism, and the unit of measurement is

not the individual, as above, but rather the family. If, for example, we measure neuroticism on a set of opposite-sex dizygotic twin pairs, the Pearson correlation is the appropriate measure of correlation to estimate twin similarity in that sample. We now have N twin pairs and variable x can be the female member of the pair's neuroticism score and y can be the male member's neuroticism score. The interclass correlation is appropriate whenever we have familial relationships where there are two classes of people, in this case males and females. Similarly, if we wanted to estimate (opposite-sex) spouse similarity, we would also use the Pearson correlation.

However, many relationships do not involve two distinct classes of people and so there is no way to determine who will be put in the x column and who will be in the y column. The most common behavioral genetic design involves the analysis of monozygotic (MZ) and same-sex dizygotic (DZ) twin pairs, and so the appropriate measure of twin similarity is the intraclass correlation. This correlation is computed from quantities obtained from an **analysis of variance**:

$$r = \frac{MS_b - MS_w}{MS_b + (s - 1)MS_w} \quad (5)$$

where MS_b is the mean-square between groups and MS_w is the mean-square within groups, with family (or pair) being the grouping factor. s is the average number of individuals per group, which is simply equal to 2 in the case of a sample of MZ or DZ twin pairs. In practice, use of the Pearson correlation instead of the intraclass correlation will not lead one very much astray, and if one computes a Pearson correlation on double-entered data, where each pair's data is entered twice, once with the first twin in the x column and once with the first twin in the y column, a convenient approximation to the intraclass correlation is obtained.

Both the above forms of correlation deal with continuous data. However, if our data are discrete, such as simple binary data like depressed versus not depressed, or have multiple categories, such as not depressed, moderately depressed, or severely depressed, we would need to employ the polychoric correlation, or the tetrachoric correlation in the special binary case, to obtain measures of familial relationship, the computation of which is beyond the scope of this short article.

Correlation Studies

Correlational research is a form of descriptive research. Because correlational designs are used extensively in educational research, they are considered separately from descriptive research and are used to assess relationships between two or more variables. These methods vary from the simple relationship between two variables to the complex interrelationships among several variables. The advantage of correlational research is that a variety of relationships can be investigated in the same study. Each of these types of studies will be illustrated.

Unlike experimental research, there is no manipulated independent variable, and only the association between variables is studied (*see* **Experimental Design; observational study**). Causal inferences cannot be made on the basis of correlational research [1]. The researcher is seeking to discover the direction and degree of relationship among variables. Test developers use correlational research when assessing the validity of an instrument. Test scores from a new instrument will often be correlated with those from an existing one with established validity evidence. A single sample is obtained and two or more variables measured, and correlational statistics are used to address the research questions. For example, a researcher may be interested in the extent of the relationship between amount of exercise and weight loss. Or a researcher may be interested in the relationship between health beliefs (measured by a questionnaire), social support (measured by a questionnaire), and adherence to medication regime (measured by periodic checkup). For these examples, the variables are continuous.

When data from more than two variables are collected on the same sample, there are two possible ways to handle the information. Correlations could be obtained between all possible pairs of variables, as might be done if the researcher is interested in the intercorrelations between scales on an instrument. A 50-item self-esteem measure was constructed to assess three aspects of self-esteem: global, social, and internal. After obtaining data on a sample of individuals, the researcher would correlate the global scale with the social and internal scales and correlate the social and internal scales. Three correlation coefficients would result from this analysis. If the researcher was not interested in simple correlation

coefficients, then to assess the relationship among the three variables a multiple correlation coefficient (*see* **Multiple Linear Regression**) could be used. This correlation is the relationship between a single dependent variable and the scores derived from a linear combination of independent variables. For example, the adherence to medication regime might be considered the dependent variable and the independent variables would be health-care beliefs and social support.

If a researcher had more than one dependent variable and more than one independent variable when investigating the relationship between these variables, then canonical correlation analysis could be used. Two linear combination or composites are formed – one for the independent variables and one for the dependent variables – and the correlation between the two composites is the canonical correlation [2] (*see* **Canonical Correlation Analysis**).

Correlational research may involve qualitative and quantitative variables. The relationships between variables that are based on the (*see* **Pearson Product Moment Correlation**) would be considered correlational, but those relationships between variables that are not based on the Pearson product-moment correlation are called **measures of association** [3]. The correlational measures involve continuous variables, ranked variables (with few ties), and dichotomous variables. Other forms of categorical variables are involved with the measures of association. Research involving one or two categorical variables (with a small number of categories) is called *correlational-comparative research* or *differential studies*. For the correlational measures, good estimates of the relationships will result when the sample size is adequate (at least 30 individuals) and when the full range of values are obtained for the participants in the research. Otherwise, the researcher is faced with a restriction of range [2]. Although a researcher will have **power** to detect statistical significance with small samples [1], the size of the **confidence interval** would be large, which indicates that the population correlation coefficient is not estimated with a great deal of accuracy. Therefore, sample sizes of at least 30 are recommended. Another consideration with continuous variables is that the range or the variability of the variables is similar. Otherwise, the magnitude of the correlation coefficient will be affected. For example, if the measure of adherence to medication regime is assessed on a scale of 1 to 6 and the other measures

2 Correlation Studies

have a range of 30 or 40 points, then there is unequal variability that will result in a lower value for the correlation coefficient. The variables could be standardized and the correlation coefficient obtained on the standardized variables, which should result in a more accurate estimate of the relationship between the variables. The reliability of the measuring instruments also affects the magnitude of the correlation coefficient. Because instruments are not perfectly reliable, there is attenuation of the correlation coefficient, which can be corrected [4]. If the self-esteem measures are not perfectly reliable, then the correlation coefficient will be smaller than if the measures had perfect reliability. The more reliable the measures, the closer the estimate of the correlation to the corrected one.

Correspondence Analysis

Introduction

Categorical variables are ubiquitous in the behavioral sciences and there are many statistical models to analyze their interrelationships (*see*, for example, **Contingency Tables; Log-linear Models; Exact Methods for Categorical Data**). Correspondence analysis (CA), is a method of **multivariate analysis** applicable to categorical data observed on two or more variables. Its objective is to obtain sets of numerical values for the categories of the variables, where these values reflect the associations between the variables and may be interpreted in a number of ways, especially visually in the form of a spatial map of the categories. Here we shall restrict attention to the correlational and graphical interpretations of CA.

In its simple form, CA analyzes the association between two categorical variables. The method can be extended in different ways to analyze three or more categorical variables, the most common variant being called multiple correspondence analysis (MCA) or *homogeneity analysis*.

Simple Correspondence Analysis: Correlational Definition

To illustrate a simple CA, consider the data on two categorical variables given in Table 1, obtained from the International Social Survey Program (ISSP) on Family and Changing Gender Roles in 1994: the country of origin of the respondent (24 different countries) and the question ‘Do you think it is wrong or not wrong if a man and a woman have sexual relations before marriage?’ with four possible responses: ‘always wrong’ (recorded as 1), ‘almost always wrong’ (2), ‘sometimes wrong’ (3), ‘never wrong’ (4), and a missing category (5), making five categories in total. The data are shown schematically in Table 1 in three different but equivalent forms:

1. The original response pattern matrix, the form typically stored in the database.
2. The individual responses coded as 29 dummy variables with zero-one coding. The resulting *indicator matrix* is subdivided into two submatrices, the first with 24 dummy variables coding

the country variable, the second with 5 dummy variables coding the responses to the substantive question about premarital sex.

3. The 24×5 contingency table which cross-tabulates the responses of all 33 590 cases in the survey.

The chi-square statistic for the contingency table is extremely high ($\chi^2 = 7101$, $df = 92$), due mainly to the large sample sizes in each country, thus indicating significant statistical association. Cramer’s V coefficient, a **measure of association** that has values between 0 (zero association) and 1 (perfect association), is equal to 0.230, indicating a fair association between countries and question responses. But what is the nature of this association? Which countries are similar in terms of their responses to this question, and which are the most different? CA attempts to answer these questions as follows.

Consider two sets of scale values $\mathbf{a} = [a_1, \dots, a_I]^T$ and $\mathbf{b} = [b_1, \dots, b_J]^T$ assigned to the $I = 24$ categories of the first variable and the $J = 5$ categories of the second variable (we write vectors as column vectors, superfix T stands for transpose). If we denote by $\mathbf{Z}_1$ and $\mathbf{Z}_2$ the two submatrices of the indicator matrix in Figure 1, then these scale values imply a pair of scores for each of the respondents in the survey, a ‘country score’ and a ‘question response score’, with all respondent scores in the vectors $\mathbf{Z}_1\mathbf{a}$ and $\mathbf{Z}_2\mathbf{b}$ respectively. Which scale values will maximize the correlation between $\mathbf{Z}_1\mathbf{a}$ and $\mathbf{Z}_2\mathbf{b}$? Since correlations are invariant with respect to linear transformations, we add the identification conditions that $\mathbf{Z}_1\mathbf{a}$ and $\mathbf{Z}_2\mathbf{b}$ are standardized to have mean 0 and variance 1, in which case the correlation to be maximized is equal to $\mathbf{a}^T\mathbf{Z}_1^T\mathbf{Z}_2\mathbf{b}$. Notice that the matrix $\mathbf{Z}_1^T\mathbf{Z}_2$ in this function is exactly the contingency table $\mathbf{N}$ in Table 1(c).

This problem is identical to **canonical correlation analysis** applied to the two sets of dummy variables. The solution is provided by the singular-value decomposition (SVD) (*see Principal Component Analysis*) of the matrix $\mathbf{N}$, where the SVD has been generalized to take into account the identification conditions imposed on the solution. It can be shown that the solution is obtained as follows, where we use the notation n_{i+} , n_{+j} and n for the row sums, column sums, and grand total respectively of the contingency table $\mathbf{N}$.

2 Correspondence Analysis

Table 1 Three forms of the same data (a) responses to the questions, coded according to the response categories; (b) coding of the same data as dummy variables, zero-one data in an indicator matrix $\mathbf{Z}$ with $24 + 5 = 29$ columns; (c) 24×5 contingency table $\mathbf{N}$ cross-tabulating the two variables ($\mathbf{N}$ has a grand total equal to 33 590, the number of cases)

(a) Calculate the matrix $\mathbf{S} = [s_{ij}]$, where

$$s_{ij} = \frac{1}{\sqrt{n}} \left(\frac{n_{ij} - \frac{n_{i+}n_{+j}}{n}}{\sqrt{\frac{n_{i+}n_{+j}}{n}}} \right). \quad (1)$$

(b) Calculate the SVD of $\mathbf{S}$

$$\mathbf{S} = \mathbf{U}\mathbf{\Gamma}\mathbf{V}^T, \quad (2)$$

where the left and right singular vectors in the columns of $\mathbf{U}$ and $\mathbf{V}$ respectively satisfy $\mathbf{U}^T\mathbf{U} = \mathbf{V}^T\mathbf{V} = \mathbf{I}$ and $\mathbf{\Gamma}$ is the diagonal matrix of positive singular values in descending order down the diagonal: $\gamma_1 \geq \gamma_2 \geq \dots \geq 0$.

(c) Calculate the two sets of optimal scale values from the first singular vectors as follows:

$$\begin{aligned} a_i &= \sqrt{n/n_{i+}}u_{i1}, \quad i = 1, \dots, I \\ b_j &= \sqrt{n/n_{+j}}v_{j1}, \quad j = 1, \dots, J. \end{aligned} \quad (3)$$

The following results can easily be verified and are standard results in CA theory:

1. The maximum correlation achieved by the solution is equal to γ_1 , the largest singular value of $\mathbf{S}$.

2. From the form (1) of the elements of $\mathbf{S}$, the total sum of squares of the matrix $\mathbf{S}$ is equal to χ^2/n , the Pearson **chi-square statistic** χ^2 for the contingency table divided by the sample size n . This quantity, also known as Pearson's mean-square contingency coefficient and denoted by ϕ^2 , is called the *(total) inertia* in CA. Notice that Cramer's $V = \sqrt{(\phi^2/d)}$, where d is equal to the smaller of $I - 1$ or $J - 1$.
3. If we continue our search for scale values, giving scores uncorrelated with the optimal ones found above but again with maximum correlation, the solution is exactly as in (3) but for the second left and right singular vectors of $\mathbf{S}$, with maximum correlation equal to γ_2 , and so on for successive optimal solutions. There are exactly d solutions ($d = 4$ in our example).

Simple Correspondence Analysis: Geometric Definition

A geometric interpretation can be given to the above results: in fact, it is the visualization aspects of CA that have made it popular as a method of

Figure 1 Asymmetric CA map of countries by response categories, showing rows in principal coordinates and columns in standard coordinates. Inertia on first axis: 0.1516 (71.7%), on second axis: 0.0428 (20.2%)

data analysis. Consider the same contingency table $\mathbf{N}$ in Table 1 and calculate, for example, the table of row proportions for each country, across the response categories (Table 2). Each of these five-component vectors, called *profiles*, defines a point in multidimensional space for the corresponding country. In fact, the *dimensionality* d of these row profiles is equal to 4 because each profile's set

of five components sums to a constant 1 (d is the same quantity calculated in previous section). Now assign a weight to each of the row profiles equal to its relative frequency in the survey, called the *mass*, given in the last column of Table 2; thus weighting the profile is proportional to its sample size. Next, define distances between the row profile vectors by the *chi-square distance*:

4 Correspondence Analysis

	Weighted average		0.145	0.068	0.139	0.571	0.078	

normalize each column of the profile matrix by dividing it by the square root of the marginal profile element (e.g., divide the first column by the square root of 0.145 and so on), and then use Euclidean distances between the transformed row profiles. Finally, look for a low-dimensional subspace that approximates the row profiles optimally in a weighted least-squares sense; for example, find the two-dimensional plane in the four-dimensional space of the row profiles, which is closest to the profile points, where closeness is measured by (mass-) weighted sum-of-squared (chi-square) distances from the points to the plane. The profile points are projected onto this best-fitting plane in order to interpret the relative positions of the countries (Figure 1).

Up to now, the geometric description of CA is practically identical to classical metric **multidimensional scaling** applied to the chi-square distances between the countries, with the additional feature of weighting each point proportional to its frequency.

But CA also displays the categories of responses (columns) in the map. The simplest way to incorporate the columns is to define fictitious unit row profiles, called *vertices*, as the most extreme rows possible; for example, the vertex profile [1 0 0 0] is totally concentrated into the response ‘always wrong’, as if there were a country that was unanimously against premarital sex. This vertex is projected onto the optimal plane, as well as the vertex points representing the other response categories, including ‘missing’. These vertex points are used as reference points for the interpretation of the country profiles.

It can be shown that this geometric version of the problem has exactly the same mathematical solution as the correlational one described previously. In fact, the following results are standard in the geometric interpretation of simple CA:

1. The column points, that is the projected vertices in Figure 1, have coordinates equal to the scale values obtained in previous section; that is,

we use the b_j 's calculated in (3) for the first (horizontal) dimension, and the similar quantities calculated from the second singular vector for the second (vertical) dimension. The b_j 's are called the *standard coordinates* (of the columns in this case).

2. The positions of the row points in Figure 1 are obtained by multiplying the optimal scale values for the rows by the corresponding correlation; that is, we use the $\gamma_1 a_i$'s for the first dimension, where the a_i 's are calculated as in (3) from the first singular vector and value, and the corresponding values for the second dimension calculated in the same way from the second singular value and vector. These coordinates of the profiles are called *principal coordinates* (of the rows in this case).
3. In the full space of the row profiles (a four-dimensional space in our example) as well as in the (two-dimensional) reduced space of Figure 1, the row profiles lie at weighted averages of the column points. For example, Sweden (S) is on the left of the display because its profile is equal to [0.039 0.015 0.046 0.854 0.046], highly concentrated into the fourth category 'never wrong' (compare this with the average profile at the center, which is [0.145 0.068 0.139 0.571 0.078]). If the response points are assigned weights equal to 0.039, 0.015, and so on, (with high weight of 0.854 on "never wrong") the weighted average position is exactly where the point S is lying. This is called the *barycentric principle* in CA and is an alternative way of thinking about the joint mapping of the points.
4. The joint display can also be interpreted as a **biplot** of the matrix of row profiles; that is, one can imagine oblique axes drawn through the origin of Figure 1 through the category points, and then project the countries onto these axes to obtain approximate profile values. On this biplot axis, the origin will correspond exactly to the average profile element (given in the last row of Table 2), and it is possible to calibrate the axis in profile units, that is, in units of proportions or percentages.
5. The inertia ϕ^2 is a measure of the total variation of the profile points in multidimensional space, and the parts of inertia $\lambda_1 = \gamma_1^2$, $\lambda_2 = \gamma_2^2$, $\dots$, called the *principal inertias*, are those parts of variation displayed with respect to each

dimension, or *principal axis*, usually expressed as percentages. The λ_k 's are the **eigenvalues** of the matrix $\mathbf{S}^T \mathbf{S}$ or $\mathbf{S} \mathbf{S}^T$. This is analogous to the decomposition of total variance in **principal component analysis**.

6. The map in Figure 1 is called the *asymmetric map* of the rows or the 'row-principal' map. An alternative asymmetric map displays column profiles in principal coordinates and row vertices in standard coordinates, called the 'column-principal' map. However, it is common practice in CA to plot the row and column points jointly as profiles, that is, using their principal coordinates in both cases, giving what is called a *symmetric map* (Figure 2). All points in both asymmetric and symmetric maps have the same relative positions along individual principal axes. The symmetric map has the advantage of spreading out the two sets of profile points by the same amounts in the horizontal and vertical directions – the principal inertias, which are the weighted sum-of-squared distances along the principal axes, are identical for the set of row profiles and the set of column profiles.

Notice in Figures 1 and 2 the curve, or *horseshoe*, traced out by the ordinal scale from 'never wrong' on the left, up to 'sometimes wrong' and 'almost always wrong' and then down to 'always wrong' on the right (see **Horseshoe Pattern**). This is a typical result of CA for ordinally scaled variables, showing the ordinal scale on one dimension and the contrast between extreme points and intermediate points on the other. Thus, countries have positions according to two features: first, their overall strength of attitude on the issue, with more liberal countries (with respect to the issue of premarital sex) on the left, and more conservative countries on the right, and second, their polarization of attitude, with countries giving higher than average in-between responses higher up, and countries giving higher than average extreme responses lower down. For example, whereas Spain (S) and Russia (RUS) have the same average attitude on the issue, slightly to the conservative side of average (horizontal dimension), the Russian responses contain relatively more intermediate responses compared to those of the Spanish responses that are more extreme in both directions (see Table 2 to corroborate this finding).

Figure 2 Symmetric CA map of countries by response categories, showing rows and columns in principal coordinates. Inertias and percentages as in Figure 1. Notice how the column points have been pulled in compared to Figure 1

Multiple Correspondence Analysis: Correlational Definition

To illustrate MCA, consider the data from four questions in the same ISSP survey, including the question studied above (A) ‘Do you think it is wrong or not wrong if a man and a woman have sexual relations before marriage?’ (B) ‘Do you think it is wrong or not wrong if a man and a woman in their early teens have sexual relations?’ (C) ‘Do you think it is wrong or not wrong if a man or a woman has sexual relations with someone other than his or her spouse?’ (D) ‘Do you think it is wrong or not wrong if adults of the same sex have sexual relations?’ All the variables have the same categories of response. We have intentionally chosen a set of variables revolving around one issue. The data structures of interest are shown in Table 3:

1. The original response categories for the whole data set of 33 590 cases, with each variable q having four response categories and a missing

category ($J_q = 5, q = 1, \dots, 4$); in general there are Q variables.

2. The $33\,590 \times 20$ indicator matrix $\mathbf{Z} = [\mathbf{Z}_1 \mathbf{Z}_2 \mathbf{Z}_3 \mathbf{Z}_4]$, with four sets of five dummy variables as columns; in general $\mathbf{Z}$ is a $n \times J$ matrix with $J = \sum_q J_q$.
3. The 20×20 block matrix $\mathbf{B}$ of all pairwise contingency tables between the four variables; $\mathbf{B}$ is called the *Burt matrix* and is square ($J \times J$) symmetric, with $\mathbf{B} = \mathbf{Z}^T \mathbf{Z}$. On the block diagonal of $\mathbf{B}$ are the diagonal matrices cross-tabulating each variable with itself, that is, with the marginal frequencies down the diagonal.

Instead of a single association we now have six associations (in general, $\frac{1}{2}Q(Q-1)$ associations) between distinct pairs of variables. To generalize the correlational definition, we use a generalization of canonical correlation analysis to more than two categorical variables. For Q variables, let $\mathbf{a}$ denote the $J \times 1$ vector of unknown scale values, subdivided as $\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_Q$ for each variable. The Q scores

Table 3 Three forms of the same multivariate data: (a) responses to the four questions, coded according to the response categories; (b) coding of the same data as dummy variables, zero-one data in an indicator matrix $\mathbf{Z}$ with $4 \times 5 = 20$ columns; (c) 20×20 Burt matrix $\mathbf{B}$ of all 5×5 contingency tables $\mathbf{N}_{qq'}$ cross-tabulating pairs of variables, including each variable with itself on the block diagonal

		0	0	0	0	1		0	0	0	0	1	0	0	0	0

for each case are in $\mathbf{Z}_1\mathbf{a}_1, \mathbf{Z}_2\mathbf{a}_2, \dots, \mathbf{Z}_Q\mathbf{a}_Q$, and the averages of these scores in $(1/Q)\mathbf{Z}\mathbf{a}$. It is equivalent to maximize the sum-of-squared correlations between the Q scores or to maximize the sum-of (or average) -squared correlations between the Q scores and the average:

$$\underset{\mathbf{a}}{\text{maximize}} \frac{1}{Q} \sum_{q=1}^Q \left[\text{cor} \left(\mathbf{Z}_q\mathbf{a}_q, \left(\frac{1}{Q} \right) \mathbf{Z}\mathbf{a} \right) \right]^2. \quad (4)$$

As before, we need an identification condition on $\mathbf{a}$, conventionally the average score $(1/Q)\mathbf{Z}\mathbf{a}$ is standardized to have mean 0 and variance 1. The solution is provided by the same CA algorithm described in formulae (1)–(3), applied either to $\mathbf{Z}$ or to $\mathbf{B}$. The standard coordinates of the columns of $\mathbf{Z}$, corresponding to the maximum singular value γ_1 , provide the optimal solution, and $\lambda_1 = \gamma_1^2$ is the attained maximum of (4). Subsequent solutions are provided by the following singular values and vectors as before. If $\mathbf{B}$ is analyzed rather than $\mathbf{Z}$, the standard coordinates of the columns of $\mathbf{B}$ (or rows, since $\mathbf{B}$ is symmetric) are identical to those of the columns of $\mathbf{Z}$, but because $\mathbf{B} = \mathbf{Z}^T\mathbf{Z}$, the singular values and eigenvalues of $\mathbf{B}$ are the squares of those of $\mathbf{Z}$, that is the eigenvalues of $\mathbf{B}$ are $\gamma_1^4, \gamma_2^4, \dots$ and so on.

In homogeneity analysis, an approach equivalent to MCA, the squared correlations $[\text{cor}(\mathbf{Z}_q\mathbf{a}_q, (1/Q)\mathbf{Z}\mathbf{a})]^2$

are called ‘discrimination measures’ and are analogous to squared (and thus unsigned) factor loadings (see **Factor Analysis: Exploratory**). Moreover, in homogeneity analysis the objective of the analysis is defined in a different but equivalent form, namely, as the minimization of the *loss function*:

$$\underset{\mathbf{a}}{\text{minimize}} \frac{1}{nQ} \sum_{q=1}^Q \left\| \mathbf{Z}_q\mathbf{a}_q - \left(\frac{1}{Q} \right) \mathbf{Z}\mathbf{a} \right\|^2, \quad (5)$$

where $\|\dots\|^2$ denotes ‘sum-of-squares’ of the elements of the vector argument. The solution is the same as (4) and the minima are 1 minus the eigenvalues maximized previously. The eigenvalues are interpreted individually and not as parts of variation – if the correlation amongst the variables is high, then the loss is low and there is high homogeneity, or *internal consistency*, amongst the variables; that is, the optimal scale successfully summarizes the association amongst the variables.

Using the ‘optimal scaling’ option in SPSS module Categories, Table 4 gives the eigenvalues and discrimination measures for the four variables in the first five dimensions of the solution (we shall interpret the solutions in the next section) (see **Software for Statistical Analyses**).

8 Correspondence Analysis

Table 4 Eigenvalues and discrimination measures (squared correlations) for first five dimensions in the homogeneity analysis (MCA) of the four questions in Table 3

Multiple Correspondence Analysis: Geometric Definition

The geometric paradigm described in section ‘Simple Correspondence Analysis: Geometric Definition’ for simple CA, where rows and columns are projected from the full space to the reduced space, is now applied to the indicator matrix **Z** or the Burt matrix **B**. Some problems occur when attempting to justify the chi-square distances between profiles and the notion of total and explained inertia. There are two geometric interpretations that make more sense: one originates in the so-called Gifi system of homogeneity analysis, the other from a different generalization of CA called *joint correspondence analysis* (JCA).

Geometry of Joint Display of Cases and Categories

As mentioned in property 3 of section ‘Simple Correspondence Analysis: Geometric Definition’, in the asymmetric CA map, each profile (in principal coordinates) is at the weighted average, or centroid, of the set of vertices (in standard coordinates). In the MCA of the indicator matrix with the categories (columns), say, in standard coordinates, and the cases (rows) in principal coordinates, each case lies at the ordinary average of its corresponding category points, since the profile of a case is simply the constant value $1/Q$ for each category of response, and zero otherwise. From (5), the optimal map is the one that minimizes the sum-of-squared distances between the cases and their response categories. It is equivalent to think of the rows in standard coordinates and the columns in principal coordinates, so that each response category is at the average of the case points who have given that response. Again the optimal display is the one that minimizes the sum-of-squared case-to-category

distances. The loss, equal to 1 minus the eigenvalue, is equal to the minimum sum-of-squared distances with respect to individual dimensions in either asymmetric map. The losses can thus be added for the first two dimensions, for example, to give the minimum for the planar display.

It is clearly not useful to think of the joint display of the cases and categories as a biplot, as we are not trying to reconstruct the zeros and ones of the indicator matrix. Nor is it appropriate to think of the CA map of the Burt matrix as a biplot, as explained in the following section.

Geometry of all Bivariate Contingency Tables (Joint CA)

In applying CA to the Burt matrix, the diagonal submatrices on the ‘diagonal’ of the block matrix **B** inflate both the chi-square distances between profiles and the total inertia by artificial amounts. In an attempt to generalize simple CA more naturally to more than two categorical variables, JCA accounts for the variation in the ‘off-diagonal’ tables of **B** only, ignoring the matrices on the block diagonal. Hence, in the two-variable case ($Q = 2$) when there is only one off-diagonal table, JCA is identical to simple CA. The weighted least-squares solution can no longer be obtained by a single application of the SVD and various algorithms have been proposed. Most of the properties of simple CA carry over to JCA, most importantly, the reconstruction of profiles with respect to biplot axes, which is not possible in regular MCA of **B**. The percentages of inertia are now correctly measured, quantifying the success of approximating the off-diagonal matrices relative to the total inertia of these matrices only.

Adjustment of Eigenvalues in MCA

It is possible to remedy partially the percentage of inertia problem in a regular MCA by a compromise between the MCA solution and the JCA objective. The total inertia is measured (as in JCA) by the average inertia of all off-diagonal subtables of **B**, calculated either directly from the tables themselves or by reducing the total inertia of **B** as follows:

$$\begin{aligned} &\text{average off-diagonal inertia} \\ &= \frac{Q}{Q-1} \left(\text{inertia}(\mathbf{B}) - \frac{J-Q}{Q^2} \right). \quad (6) \end{aligned}$$

Parts of inertia are then calculated from the eigenvalues λ_s^2 of **B** (or λ_s of **Z**) as follows: for each

$\lambda_s \geq 1/Q$ calculate the adjusted inertias

$$\left(\frac{Q}{Q-1} \right)^2 \left(\lambda_s - \frac{1}{Q} \right)^2$$

and express these as percentages of (6). Although these percentages underestimate those of JCA, they

dramatically improve the results of MCA and are recommended in all applications of MCA.

In our example, the total inertia of **B** is equal to 1.1659 and the first five principal inertias are such that $\lambda_s \geq 1/Q$, that is, $\lambda_s^2 \geq 1/Q^2 = 1/16$. The different possibilities for inertias and percentages of inertia are given in Table 5. Thus, what appears to be a percentage explained in two dimensions of 29.9% (= 12.9 + 11.0) in the analysis of the indicator matrix **Z**, or 39.7% (= 23.0 + 16.7) in the analysis of the Burt matrix **B**, is shown to be at least 86.9% (= 57.6 + 29.3) when the solution is rescaled. The JCA solution gives only a slight extra benefit in this case, with an optimal percentage explained of 87.4%, so that the adjusted solution is practically optimal.

Figure 3 shows the adjusted MCA solution, that is, in adjusted principal coordinates. The first dimension lines up the four ordinal categories of each question in their expected order (accounting for 57.6% of the inertia), whereas the second dimension opposes all the missing categories against the rest (29.3% of inertia). The positions of the missing values on the

Table 5 Eigenvalues (principal inertias) of the indicator matrix and the Burt matrix, their percentages of inertia, the adjusted inertias, and their lower bound estimates of the percentages of inertia of the off-diagonal tables of the Burt matrix. The average off-diagonal inertia on which these last percentages are based is equal to $4/3(1.1659 - 16/16) = 0.2212$

Dimension	Eigenvalue of Z	Percentage explained	Eigenvalue of B	Percentage explained	Adjusted eigenvalue	Percentage explained
1	0.5177	12.9	0.2680	23.0	0.1274	57.6
2	0.4409	11.0	0.1944	16.7	0.0648	29.3
3	0.3535	8.8	0.1249	10.7	0.0190	8.6
4	0.2881	7.2	0.0830	7.1	0.0026	1.2
5	0.2608	6.5	0.0681	5.8	0.0002	0.0

Table 6 Category scale values (standard coordinates) on first dimension (see Figure 3), and their linearly transformed values to have 'not wrong at all' categories equal to 0 and highest possible score (sum of underlined scale values) equal to 100

	Always wrong	Almost always wrong	Only sometimes wrong	Not wrong at all	Missing
(a) Sex before marriage	<u>2.032</u> 27.9	1.167 19.2	0.194 9.5	-0.748 0.0	0.333 10.9
(b) Sex teens under 16	<u>0.976</u> 25.4	-0.813 7.4	-1.463 0.9	-1.554 0.0	-0.529 10.3
(c) Sex other than spouse	<u>0.747</u> 23.5	-1.060 5.3	-1.414 1.8	-1.591 0.0	-0.895 7.0
(d) Sex two people of same sex	<u>1.001</u> 23.2	-0.649 6.6	-0.993 3.2	-1.310 0.0	-0.471 8.4

10 Correspondence Analysis

first axis will thus provide estimated scale values for missing data that can be used in establishing a general attitude scale of attitudes to sex. The scale values on the first dimension can be transformed to have

more interpretable values, for example, each category 'always wrong' can be set to 0 and the upper limit of the case score equalized to 100 (Table 6). The process of redefining the scale in this way is invariant

Figure 3 MCA map of response categories (analysis of Burt matrix): first (horizontal) and second (vertical) dimensions, using adjusted principal inertias. Inertia on first axis: 0.1274 (57.6%), on second axis: 0.0648 (29.3%). Labels refer to variable A to D, with response categories 1 to 4 and missing (M)

Figure 4 Positions of supplementary country-gender points in the map of Figure 3. Country abbreviations are followed by m for male or f for female

with respect to the particular scaling used: standard, principal, or adjusted principal.

Having identified the optimal scales, subgroups of points may be plotted in the two-dimensional map; for example, a point for each country or a point for a subgroup within a country such as Italian females or Canadian males. This is achieved using the barycentric principle, namely, that the profile position is at the weighted average of the vertex points, using the profile elements as weights. This is identical to declaring this subgroup a supplementary point, that is, a profile that is projected onto the solution subspace. In Figure 4 the positions of males and females in each country are shown. Apart from the general spread of the countries with conservative countries (e.g., Philippines) more to the right and liberal countries more to the left (e.g., Germany), it can be seen that the female groups are consistently to the conservative side of their male counterparts and also almost always higher up on the map, that is, there are also more nonresponses amongst the females.

Further Reading

Benzécri [1] – in French – represents the original material on the subject. Greenacre [4] and [7] both give introductory and advanced treatments of the French approach, the former being a more encyclopedic treatment of CA and the latter including other methods of analyzing large sets of categorical data. Gifi [3] includes CA and MCA in

the framework of nonlinear multivariate analysis, a predominantly Dutch approach to data analysis. Greenacre [5] is a practical user-oriented introduction. Nishisato [8] provides another view of the same methodology from the viewpoint of quantification of categorical data. The edited volumes by Greenacre and Blasius [6] and Blasius and Greenacre [2] are self-contained state-of-the-art books on the subject, the latter volume including related methods for visualizing categorical data.

Co-twin Control Methods

Overview

The co-twin control method is one of the most simple and elegant research designs available in the behavioral sciences. The method uses differences within twin pairs to examine the association between a putative environmental risk factor and an outcome variable. The unique value of the design is that numerous potential confounding factors, such as age and parental socioeconomic status, are matched and cannot confound the risk factor–outcome association. This design can be extremely efficient for examining risk factor–outcome associations compared to unmatched designs [12]. When the within-pair comparisons are restricted to monozygotic (MZ) twins, who share 100% of their genetic material, the risk factor–outcome association is completely controlled for confounding due to genetic factors.

The central feature of the design is a focus on within-pair differences among either risk factor or outcome discordant pairs. In most co-twin control studies, within-pair discordance is defined as a dichotomous variable where one twin has the risk factor (i.e., smokes cigarettes) while the other twin does not (i.e., nonsmoker). Co-twin control studies that use an experimental approach create the discordant pairs by randomly assigning one member of a pair to the active treatment group and the other member of the pair to the control group. Experimental co-twin control studies then compare within-pair differences in an outcome variable among the treatment and control groups. Feeding studies have used this design extensively to examine the effects of altering diet on weight and body fat distribution [2].

Observational co-twin control studies can be formulated in two different ways, depending on how the twin sample is assembled. A cohort formulation begins by identifying pairs who are discordant for an environmental risk factor and then compares within-pair differences in the outcome variable. An example of the cohort co-twin control approach is the Finnish study of lumbar disc degeneration in 45 twin pairs discordant for lifetime driving exposure [1]. The so-called case-control co-twin formulation starts by defining pairs discordant for an outcome variable and then examines within-pair differences

for an environmental risk factor. The case-control co-twin design is especially valuable when the outcome being investigated is rare and the twins are derived from treatment seeking samples or volunteers. The case-control co-twin design was used in a recent study of regional cerebral blood flow in 21 MZ twin pairs discordant for chronic fatigue syndrome [10].

Statistical Methods

The statistical analysis of co-twin control studies uses well-established methods for matched data to account for the lack of independence between members of a twin pair. We present the basic analytic methods that can be applied to co-twin control studies with a discordant environmental risk factor and a continuous or dichotomous outcome variable.

Dichotomous Environmental Risk Factor and a Continuous Outcome Variable

The analysis begins by calculating the mean value of the outcome variable among all discordant twin pairs, separately in those exposed and not exposed to the risk factor. These means are useful descriptive statistics in helping to understand the pattern of association between the risk factor and the outcome. Formal statistical testing is conducted on the basis of the within-pair mean difference in those exposed and not exposed. The standard error for the within-pair mean difference is used to calculate the matched pair *t* Test and 95% **confidence intervals**. When information on twin zygosity is available, it is informative to repeat these analyses separately in MZ and dizygotic (DZ) pairs. Zygosity-specific patterns of within-pair mean differences can be helpful in understanding the risk factor–outcome association. If the within-pair mean differences are not equal to zero and similar in MZ and DZ pairs, this would suggest that the risk factor–outcome association is not confounded by familial or genetic influences. However, if after zygosity stratification a sizable within-pair difference is present in DZ pairs but completely absent in MZ pairs, this would strongly suggest genetic confounding [4]. Intermediate patterns in which the size of the MZ within-pair difference is reduced, but is still present, imply a modest degree of genetic confounding. Differences in the MZ and DZ within-pair mean

difference can be formally tested for heterogeneity using a two-sample t Test.

Dichotomous Environmental Risk Factor and a Dichotomous Outcome Variable

The analysis of dichotomous outcomes in the co-twin control study starts by estimating the prevalence of the outcome in twins exposed and unexposed to the risk factor. This descriptive information is valuable for interpreting study findings since it is often difficult to present the details of a within-pair analysis of dichotomous outcomes in a simple table. Estimation of the strength of the association between the risk factor and outcome is based on the matched pair **odds ratio (OR)**. The matched pair odds ratio uses the count of the number of discordant twin pairs according to the pair configuration on the risk factor and outcome. With a dichotomous risk factor and outcome, there are four possible pair configurations to count: n_{11} = the number of risk factor discordant pairs in which both members have the outcome; n_{10} = the number of risk factor discordant pairs in which the twin exposed to the risk factor has the outcome and the twin not exposed does not have the outcome; n_{01} = the number of risk factor discordant pairs in which the twin exposed to the risk factor does not have the outcome and the twin not exposed has the outcome; n_{00} = the number of risk factor discordant pairs in which neither twin has the outcome. The odds ratio is simply n_{10}/n_{01} . McNemar's X^2 test for matched pairs (*see Paired Observations, Distribution Free Methods*) can be used to test the significance of the odds ratio, and the standard error for the matched pair odds ratio can be used to derive 95% confidence intervals.

If zygosity information is available, the matched pair statistical analysis can be repeated after stratifying by zygosity. This analysis obtains separate odds ratio estimates of the risk factor–outcome association in MZ and DZ pairs. Interpretation of these zygosity-specific matched pair odds ratios is directly analogous to that used when examining within-pair mean differences [9]. When both the MZ and DZ risk factor–outcome odds ratios are greater than 1 and of similar magnitude, this suggests the absence of genetic confounding. Conversely, when the DZ odds ratio is elevated while the MZ odds ratio approaches 1, this strongly suggests that the risk factor–outcome association is due to the confounding influence of

genetic factors. Testing the difference between the stratum-specific matched pair odds ratios involves using the risk factor–outcome discordant pairs in a Pearson's X^2 test with 1 degree of freedom (*see Contingency Tables*).

An Illustration: A Co-twin Control Analysis of Military Service in Vietnam and Posttraumatic Stress Disorder (PTSD)

The co-twin control analysis is illustrated using data derived from the Vietnam Era Twin Registry [6]. The Registry was established in the 1980s and contains male–male veteran twin pairs born between 1939 and 1957 who served on active duty military service during the Vietnam era (1965–1975). In 1987, a mail/telephone survey collected data on a number of demographic, behavioral, and health characteristics including zygosity, service in Vietnam, and PTSD symptoms.

Zygosity was determined using a questionnaire similarity algorithm supplemented with limited blood group typing from the military records [5]. Service in Vietnam was based on a single yes/no question item. Fifteen question items inquired about the frequency of PTSD symptomology in the past 6 months; twins could rank frequency according to a five-level ordinal response ranging from never = 1 to very often = 5. The items were summed to create a symptom scale with higher values representing a greater likelihood of PTSD symptoms. The statistical analysis first examines the relationship of Vietnam service to the PTSD symptom scale where the scale is considered a continuous outcome variable; the analysis is then repeated after making the PTSD scale a dichotomy, with the upper quartile defined as those more likely to have PTSD.

Table 1 presents the within-pair mean differences for the PTSD symptom scale according to service in Vietnam. There were a total of 1679 twin pairs in the Registry, where one member of the pair served in Vietnam but their twin sibling did not. In all twins, the mean PTSD symptom scale was higher in those who served in Vietnam compared to those who served elsewhere; the within-pair mean difference was 5 (95% CI 4.4,5.6) with a matched pair t Test (*see Catalogue of Parametric Tests*) of 16.6 ($p < .001$). Analysis stratified by zygosity found similar within-pair mean differences in MZ

Table 1 Co-twin control analysis of Vietnam service discordant pairs and mean levels of PTSD symptoms

Sample	Number of Vietnam discordant pairs	Mean level of PTSD symptoms for Vietnam service		Within-pair mean difference in PTSD symptoms	95% CI	Matched pair <i>t</i> Test		Heterogeneity	
		Vietnam service	No service in Vietnam			<i>t</i>	<i>P</i> value	<i>t</i>	<i>P</i> value
All pairs	1679	29.6	24.6	5.0	4.4,5.6	16.6	<0.001		
MZ	846	29.7	24.5	5.2	4.4,6.0	13.0	<0.001	0.67	0.50
DZ	833	29.5	24.7	4.8	3.9,5.7	10.6	<0.001		

Table 2 Co-twin control analysis of Vietnam service discordant pairs and the presence of high levels of PTSD symptoms

Sample	Number of Vietnam discordant pairs	PTSD prevalence ^a		Pair configuration ^b						McNemar's test		Heterogeneity	
		Vietnam service (%)	No service in Vietnam (%)	<i>n</i> ₁₁	<i>n</i> ₁₀	<i>n</i> ₀₁	<i>n</i> ₀₀	OR	95% CI	<i>X</i> ²	<i>P</i> value	<i>X</i> ²	<i>P</i> value
All pairs	1679	34.8	15.5	148	437	113	981	3.9	3.1,4.8	191.0	<0.001	0.37	0.54
MZ	846	34.0	14.4	69	219	53	505	4.1	3.1,5.6	101.4	<0.001		
DZ	833	35.7	16.7	79	218	60	476	3.6	2.7,4.8	89.9	<0.001		

^aThe prevalence of PTSD was defined as a PTSD score greater than 32, which represents the upper quartile of the PTSD scale distribution.

^b*n*₁₁ = number of Vietnam discordant pairs in which both twins have PTSD; *n*₁₀ = number of Vietnam discordant pairs in which the twin with service in Vietnam has PTSD and the twin without Vietnam service does not have PTSD; *n*₀₁ = number of Vietnam discordant pairs in which the twin with service in Vietnam does not have PTSD and the twin without Vietnam service has PTSD; *n*₀₀ = number of Vietnam discordant pairs in which neither twin has PTSD.

and DZ pairs. The comparison of heterogeneity of the MZ and DZ within-pair mean differences was not significant ($p = .503$), providing little evidence of genetic confounding.

Table 2 presents the matched pairs analysis of service in Vietnam and the dichotomous indicator of PTSD symptoms. Overall, 35% of those who served in Vietnam were in the upper quartile of the PTSD symptom scale, while only 16% of those who did not serve in Vietnam had similarly high levels of PTSD symptoms. The matched pair odds ratio indicates that twins who served in Vietnam were nearly 4 times more likely to have high levels of PTSD symptoms compared to their twin who did not serve. The within-pair difference in PTSD was highly significant based on the McNemar test ($X^2 = 191.00$; $p < .001$). Stratification by zygosity demonstrated that the effects were similar in both MZ and DZ pairs; the difference in the matched pair odds ratios

in MZ and DZ pairs was not statistically significant ($X^2 = 0.37$, $p = .543$).

More Advanced Methods

For co-twin control designs using the experimental or cohort approach with risk factor discordant twin pairs, there is now a wide range of methods for clustered data that can be used to analyze twins [7, 11]. Duffy [3] has described how co-twin control studies can be analyzed using **structural equation models**. Methods such as random effects regression (see **Linear Multilevel Models; Generalized Linear Mixed Models**) models and **generalized estimating equations** are readily adapted to the analysis of twins [14]. These methods are extremely flexible and allow additional covariates to be included in the regression model as both main-effects and interaction terms.

Options are available to examine outcome variables that can take on virtually any structure, including continuous, dichotomous, ordinal, and censored. Further extensions allow the simultaneous analysis of multiple outcomes as well as longitudinal analysis of repeated measures over time (*see Longitudinal Data Analysis; Repeated Measures Analysis of Variance*). These more complex applications can also go beyond the discordant co-twin control method to incorporate all types of exposure patterns within twin pairs [8]. However, application of these more sophisticated analyses should be done with great care to make sure that the appropriate statistical model is used [13].

Counterbalancing

Counterbalancing, in its simplest form, is the procedure of varying the order in which subjects receive treatments in order to minimize the bias potentially associated with the treatment order. When each participant receives more than one treatment (as in a **crossover design** [6]), counterbalancing is necessary to ensure that treatment effects are not confounded with **carryover** effects. One well-known example is the Pepsi–Coke taste test, common in the 1980s. Half the participants were given Pepsi first, and half the participants were given Coke first. Participants were also offered a cracker before trying the second cola. The random ordering neutralized the order effect, while the cracker minimized the carryover effect.

When and Why Counterbalancing is Needed

In some experiments, it may be suspected that the outcome of a given treatment may be affected by the number of treatments preceding it, and/or the treatment immediately preceding it [2]. Counterbalancing is used to control these effects. If a subject is given three treatments, then the results may be affected by the order of the treatments, carryover from the prior treatments, and in some cases where a task is repeated, subjects may learn to complete the task better over time. This learning effect, known more formally as asymmetric skill transfer, is discussed further in [7].

In the example of the cola taste test mentioned above, thirsty participants may be more likely to choose the first drink given. Similarly, if the first drink satisfies the thirst, then the lack of thirst may affect how favorably the participant views the second drink. A devoted cola fan, after taking the taste test multiple times, might even learn to distinguish between the two colas and pick the one identified as his or her favorite each time, even if that cola would not have been the one selected in the absence of prior knowledge.

While this is a simplistic example, these effects can drastically alter the outcome of experiments if ignored. There are, however, some limitations to when counterbalancing can be used. Manipulations

must be reversible. For instance, suppose that the two available treatments for a certain medical condition are surgery and no surgery. Patients receiving surgery first would likely experience enormous carryover effect, while those receiving no surgery, then surgery, would be expected to have little, if any, carryover. Counterbalancing would not balance out these effects. Instead, a between-subjects design should be considered.

Complete Counterbalancing

Complete counterbalancing requires that every set of combinations occurs equally often (in the same number of subjects). This is often considered the optimal method. With only two treatments, A and B, half the participants would receive treatments in the order AB, and the other half would receive BA. With three treatments, there are six orders, specifically ABC, ACB, BAC, BCA, CAB, and CBA. With complete counterbalancing, each of these six orders would be represented in a given number of subjects, thereby requiring equal numbers of subjects in all six groups. With more treatments, the number of permutations grows dramatically. In fact, for k treatments, there are $k!$ different combinations. This potentially large number of permutations can be one of the primary drawbacks to complete counterbalancing.

Incomplete Counterbalancing

Incomplete, or partial, counterbalancing is often used when complete counterbalancing is not feasible. The most prevalent type is a **Latin square**. Further details of the Latin Square construction are given in [2]. It should be noted that Latin squares of order n are extremely numerous for $n > 3$. Indeed, the first row can be any one of $n!$ permutations. After the first row is chosen, there are approximately $n!/e$ choices for the second row (e is the base for the natural logarithm). A simple Latin square provides a set of treatment orders in which every treatment is given first once, second once, and so on. In a simple example with four treatments and four subjects, treatments A, B, C, and D would be given in order as follows:

Subject 1:	A	B	C	D
Subject 2:	B	C	D	A
Subject 3:	C	D	A	B
Subject 4:	D	A	B	C

2 Counterbalancing

While every treatment appears in every time point exactly once, it should be noted that treatment order does not vary in a simple Latin square. Every treatment C is followed by treatment D, and so on. While this method can account for both the order effect and the learning effect, it does not counteract the carryover effect. A better method is a balanced Latin square. In this type of Latin square, each treatment immediately follows and immediately precedes each other treatment exactly once, as shown here:

Subject 1:	A	B	D	C
Subject 2:	B	C	A	D
Subject 3:	C	D	B	A
Subject 4:	D	A	C	B

It should be noted that balanced squares can be constructed only when the number of treatments is even. For odd numbers of treatments, a mirror image of the square must be constructed. Further details are given in [3]. Latin squares are used when the number of subjects, or blocks of subjects, equals the number of treatments to be administered to each. When the number of sampling units exceeds the number of treatments, multiple squares or rectangular arrays should be considered, as discussed in [8]. In the event that participants receive each treatment more than once, reverse counterbalancing may be used. In this method, treatments are given in a certain order and then in the reverse order. For example, a subject would receive treatments ABCCBA or CBAABC. A variation on this theme, in which subjects were randomized to be alternated between treatments A and B in the order ABABAB... or BABABA..., was recently used to evaluate itraconazole to prevent

fungal infections [5] and critiqued [1]. It is also possible to randomize treatments to measurement times, for a single individual or for a group [4].

Counterfactual Reasoning

The term ‘counterfactual conditional’ is used in logical analysis to refer to any expression of the general form: ‘If A were the case, then B would be the case’, and in order to be counterfactual or contrary to fact, A must be false or untrue in the world. Examples abound. ‘If kangaroos had no tails, they would topple over’ [7]. ‘If an hour ago I had taken two aspirins instead of just a glass of water, my headache would now be gone’ [14]. Perhaps the most obnoxious counterfactuals in any language are those of the form: ‘If I were you, I would. . .’

Lewis [6] observed the connection between counterfactual conditionals and references to causation. He finds these logical constructions in the language used by Hume in his famous discussion of causation.

Hume defined causation twice over. He wrote, ‘We may define a cause to be *an object followed by another, and where all the objects, similar to the first, are followed by objects similar to the second*. Or, in other words, *where, if the first object had not been, the second never had existed*’ ([6], italics are Lewis’s).

Lewis draws attention to the comparison between the factual first definition where one object is followed by another and the counterfactual second definition where, counterfactually, it is supposed that if the first object ‘had not been’, then the second object would not have been either.

It is the connection between counterfactuals and causation that makes them relevant to behavioral science research. From the point of view of some authors, it is difficult, if not impossible, to give causal interpretations to the results of statistical calculations without using counterfactual language, for example [3, 10, 11, 14]. Other writers are concerned that using such language gives an emphasis to unobservable entities that is inappropriate in the analysis and interpretation of empirical data, for example [2, 15]. The discussion here accepts the former view and regards the use of counterfactuals as a key element in the causal interpretation of statistical calculations.

A current informal use of the term counterfactual is as a synonym for control group or comparison. What is the counterfactual? This usage usually just means, ‘To what is the treatment being compared?’ It is a sensible question because the effect of a treatment is always relative to some other treatment. In behavioral science research, this simple observation can be

quite important, and ‘What is the counterfactual?’ is always worth asking and answering.

I begin with a simple observation. Suppose that we find that a student’s test performance changes from a score of X to a score of Y after some educational intervention. We might then be tempted to attribute the pretest–posttest change, $Y - X$ to the intervening educational experience – for example, to use the gain score as a measure of the improvement due to the intervention. However, this is behavioral science and not the tightly controlled ‘before-after’ measurements made in a physics laboratory. There are many other possible explanations of the gain, $Y - X$. Some of the more obvious are: simple maturation, other educational experiences occurring during the relevant time period, and differences in either the tests or the testing conditions at pre- and posttests. Cook and Campbell [1] provide a classic list of ‘threats to internal validity’ that address many of the types of alternative explanations for apparent causal effects of interventions (see **Quasi-experimental Designs**).

For this reason, it is important to think about the real meaning of the attribution of cause. In this regard, Lewis’s discussion of Hume serves us well. From it we see that what is important is what the value of Y *would have been* had the student *not had* the educational experiences that the intervention entailed. Call this score value Y^* . Thus, enter counterfactuals. Y^* is not directly observed for the student, for example, he or she *did have* the educational intervention of interest, so asking for what his or her posttest score *would have been* had he or she *not had it* is asking for information collected under conditions that are contrary to fact. Hence, it is not the difference $Y - X$ that is of causal interest, but the difference $Y - Y^*$, and the gain score has a causal significance only if X can serve as a substitute for the counterfactual Y^* . In physical-science laboratory experiments, this *counterfactual substitution* is often easy to make, but it is rarely believable in many behavioral science applications of any consequence. In fact, justifying the substitution of data observed on a control or comparison group for what the outcomes would have been in the treatment group had they not had the treatment, that is, justifying the counterfactual substitution, is the key issue in all of causal inference.

A formal statistical model for discussing the problem of estimating causal effects (of the form $Y - Y^*$ rather than $Y - X$) was developed by Neyman [8, 9] (for randomized experiments), and

2 Counterfactual Reasoning

by Rubin [13, 14] (for a wider variety of causal studies). This formal model is described in [3] and compared to the more usual statistical models that are appropriate for descriptive rather than causal inference. This approach to defining and estimating causal effects has been applied to a variety of research designs by many authors including [4, 5, 12] and the references therein.

Counternull Value of an Effect Size

The counternull value of any obtained **effect size** was introduced as a new statistic in 1994 [5]. Its purpose was to aid our understanding and reporting of the results of research. One widespread error in the understanding and reporting of data in the behavioral sciences has been the tendency to equate failure to reject the null hypothesis with evidence for the truth of the null hypothesis. For example, suppose an investigator compares the results of a new intervention with the results of the standard intervention in a randomized experiment. Suppose further that the mean benefit scores for the participants were 5 units and 2 units for the new versus old interventions, respectively, with a within-group standard deviation for each condition of 6.0. A commonly used index of effect size is the difference between the means of the two groups being compared divided by the within-group standard deviation or $(\text{Mean}_1 - \text{Mean}_2)/SD$ [1, 2], and [3]. For our present example then, our effect size, Hedges's g , would be $(5 - 2)/6.0 = 0.50$ or a one-half unit of a standard deviation, a quite substantial effect size. Further, suppose that each of our conditions had a dozen participants, that is, $n_1 = n_2 = 12$ so the value of the t Test comparing the two conditions would be 1.22 with a one-tailed p of .12, clearly 'not significant' by our usual criteria. At this point, many investigators would conclude that, given a null hypothesis that could not be rejected, 'there is no difference between the two conditions.' That conclusion would be incorrect.

For the frequent situation in which the value of the condition differences is 0.00 under the null hypothesis, the counternull value of the obtained effect size is simply $2 \times$ effect size or $2g = 2(0.50) = 1.00$ in our example. The interpretation is that, on the basis of our obtained effect size, the null hypothesis that $g = 0.00$ in the population from which we have sampled is no more likely to be true than that the population value of $g = 1.00$. Indeed, a population value of $g = 0.99$ is *more* likely to be true than that the population value of $g = 0.00$.

The obtained effect size estimate always falls between the null value of the effect size and the

counternull value. In addition, for any effect size estimate that is based on symmetric distributions such as the normal or t distributions (e.g., g , d , Δ) (see **Catalogue of Probability Density Functions**), the obtained effect size falls exactly halfway between the null value of the effect size and the counternull value. For these effect size estimates, the null value is typically 0.00, and in such cases, the counternull value is simply twice the obtained effect size. In general, when dealing with effect sizes with asymmetric distributions (e.g., Pearson's correlation r), it is best to transform the effect size to have a symmetric distribution (e.g., r should be transformed to Fisher's Z_r). After calculating the counternull on the symmetric scale of Z_r , we then transform back to obtain the counternull on the original scale of r .

In this framework, when we note that 'the obtained effect size (0.50 in our example) is not significantly different from the null value' (0.00 in our example), the counternull value forces us to confront the fact that though the assertion is true, it is no more true than the assertion that 'the obtained effect size is not significantly different from the counternull value' (1.00 in this example).

(1) shows a general procedure for finding the counternull value of the effect size for any effect size with a symmetric reference distribution (e.g., the normal or t distribution) no matter what the effect size (ES) magnitude is under the null:

$$ES_{\text{counternull}} = 2ES_{\text{obtained}} - ES_{\text{null}}. \quad (1)$$

Since the effect size expected under the null is zero in so many applications, the value of the counternull is often simply twice the obtained effect size or $2ES_{\text{obtained}}$.

An example in which the null effect size is not zero might be the case of a study testing a new treatment against a placebo control. The currently standard treatment is known to have an average effect size d of 0.40. The null hypothesis is that the new treatment is not different from the old. The d obtained for the new treatment is 0.60 but, with the size of study employed, that d was not significantly greater than the standard d of 0.40. The counternull value of the effect size in this example, however, is $2ES_{\text{obtained}} - ES_{\text{null}} = 2(0.60) - 0.40 = 0.80$. The evidence for a d of 0.80, therefore, is as strong as it is for a d of 0.40.

The counternull value of an effect size can be employed in other contexts as well. For example,

2 Counternull Value of an Effect Size

sometimes when sample sizes are very large, as in some **clinical trials**, highly significant results may be associated with very small effect sizes. In such situations, when even the counternull value of the obtained effect size is seen to be of no practical import, clinicians may decide there is insufficient benefit to warrant introducing a new and possibly very expensive intervention. Finally, it should be noted that the counternull values of effect sizes can be useful in multivariate cases, as well as in contrast analyses [4] and [5].

Covariance

Covariance is a descriptive measure of the extent to which two variables vary together. Figure 1 shows an example from UK women's athletic records from 1968 to 2003 [2]. Shorter 1500 m times go together with longer high-jump distances (Figure 1a), but shorter 200 m times (Figure 1b). There is no direct causal link – covariance does not imply causality. However, performance in all events tends to improve with time, thus leading to associations, such that shorter times in running events go with longer distances in jump events.

The covariance unit of measurement is the product of the units of measurement of the two variables. Thus, covariance changes if the unit of measurement is changed, say from seconds to minutes. Covariances in different units (a) cannot be meaningfully compared and (b) give no idea of how well a straight line fits the data. For example, the data in Figure 1(a) gives covariance (high jump, 1500 m) = $-0.0028 \text{ m min} = -0.17 \text{ m sec}$, with Pearson's $r = -0.53$. The data in Figure 1(b) gives covariance (200 m, 1500 m) = $+0.017 \text{ sec min} = 1.03 \text{ sec}^2$, with Pearson's $r = +0.59$.

Calculation

The covariance of N pairs of variables X and Y , cov_{XY} , is defined by (1) [1]:

$$\text{cov}_{XY} = \frac{\sum (X - \bar{X})(Y - \bar{Y})}{N - 1}. \quad (1)$$

However, it is most directly and accurately computed using (2):

$$\text{cov}_{XY} = \frac{\sum XY - \frac{\sum X \sum Y}{N}}{N - 1}. \quad (2)$$

Uses of Covariance and Relation to Pearson's r

The main use of covariance is as a building block for **Pearson's product moment correlation coefficient**, r , which measures the covariance relative to the **geometric mean** of the standard deviations of X and Y , s_X , s_Y , as shown in (3),

$$r = \frac{\text{cov}_{XY}}{s_X s_Y} \text{ or } r^2 = \frac{\text{cov}_{XY}^2}{\text{var}_X \text{var}_Y}. \quad (3)$$

Pearson's r has the advantage of being independent of the unit of measurement of X and Y . It is also the basis of hypothesis tests of whether the relation between Y and X is statistically significant. Consequently, Pearson's r is used when comparing the extent to which pairs of variables are associated. A higher magnitude of r (positive or negative) always indicates a stronger association. Equally useful, r^2 , the proportion of variance accounted for by the linear relation between X and Y , is a measure of covariance

Figure 1 UK women's athletic performance from 1968 to 2003 to demonstrate covariance. (a) shows negative relation between 1500 m and high-jump performance. (b) shows positive relation between 1500 m and 200 m performance

2 Covariance

relative to the variance of X and Y , var_X , var_Y (as shown in the alternative form of (3)).

When there are more than two variables, the covariance matrix is important. It is a square matrix with variance of i th variable on the diagonal and covariance of i th and j th variable in column i row j . The covariance matrix underpins multivariate analyses, such as **multiple linear regression** and **factor analysis**.

Covariance is only useful as a stepping stone to correlation or multivariate analyses.

Covariance Matrices: Testing Equality of

Parametric statistical inference requires distributional assumptions to be made about the observed data, and most multivariate inferential procedures assume that the data have come from either one or more multivariate normal populations (*see Catalogue of Probability Density Functions*). Moreover, in hypothesis-testing situations that involve more than one population, a further assumption on which the tests depend is that the dispersion matrices are equal in all populations. This assumption is made, for example, in Hotelling's T^2 test for equality of mean vectors in two populations and in all **multivariate analysis of variance** (MANOVA) situations, including the one-way case in which equality of mean vectors in $g(>2)$ populations is tested. Furthermore, the same assumption is made in various descriptive multivariate techniques such as **discriminant analysis** and **canonical discriminant analysis**. In any practical situation, of course, the sample **covariance matrices** will only be estimates of the corresponding population dispersion matrices and will exhibit sampling variability. So it is important to have a reliable test that determines whether a set of sample covariance matrices could have come from multivariate normal populations with a common dispersion matrix.

Suppose that we have p -variate samples of sizes $n_1, n_2, \dots, n_g$ from g multivariate normal populations, and that $\mathbf{S}_i$ is the unbiased (i.e., divisor $n_i - 1$) sample covariance matrix for population i ($i = 1, \dots, g$). Let $\mathbf{S}$ be the pooled within-sample covariance matrix, that is, $(N - g)\mathbf{S} = \sum_{i=1}^g (n_i - 1)\mathbf{S}_i$ where $N = \sum_{i=1}^g n_i$. Wilks [4] was the first to give a test of the null hypothesis that all the population dispersion matrices are equal against the alternative that at least one is different from the rest, and his test is essentially the one obtained using the likelihood ratio principle. The test statistic is $M = (N - g) \log_e |\mathbf{S}| - \sum_{i=1}^g (n_i - 1) \log_e |\mathbf{S}_i|$ where $|\mathbf{D}|$ denotes the determinant of matrix $\mathbf{D}$, and if the null hypothesis of equality of all population matrices is true then for large samples M has an approximate Chi-squared distribution on $f_1 = p(p + 1)(g - 1)/2$ degrees of freedom. Box [1] showed that a more accurate approximation to this distribution is obtained on multiplying M

by the factor $1 - (2p^2 + 3p - 1)/(6(p + 1)(g - 1))(\sum_{i=1}^g 1/(n_i - 1) - 1/(N - g))$. Values of the test statistic greater than the upper $100\alpha\%$ critical point of the Chi-squared distribution on f_1 degrees of freedom imply that the null hypothesis should be rejected in favor of the alternative at the $100\alpha\%$ significance level. Commonly α is chosen to be 0.05 (for a test at the 5% significance level), in which case the critical point is the value above which 5% of the Chi-squared (f_1) distribution lies. This is the most common test used for this situation, but an alternative approximation to the null distribution, and references to associated tables of critical values, are given in Appendix A8 of [2].

To illustrate the calculations, consider the example given by Morrison [3] relating to reaction times of 32 male and 32 female subjects when given certain visual stimuli. For two of the variables in the study, the unbiased covariance matrices for the males and females were $\mathbf{S}_1 = \begin{pmatrix} 4.32 & 1.88 \\ 1.88 & 9.18 \end{pmatrix}$ and $\mathbf{S}_2 = \begin{pmatrix} 2.52 & 1.90 \\ 1.90 & 10.06 \end{pmatrix}$, respectively. This gives the pooled covariance matrix $\mathbf{S} = \begin{pmatrix} 3.42 & 1.89 \\ 1.89 & 9.62 \end{pmatrix}$, and the determinants of the three matrices are found to be $|\mathbf{S}_1| = 36.123$, $|\mathbf{S}_2| = 21.741$, $|\mathbf{S}| = 29.328$. Here, $p = 2$, $g = 2$ and $N = 64$, so $M = 62 \log_e 29.328 - 31(\log_e 36.123 + \log_e 21.741) = 2.82$ and the Box correction factor is $1 - (2 \times 4 + 3 \times 2 - 1)/(6 \times 3 \times 1) \times (1/31 + 1/31 - 1/62) = 1 - 13/18 \times 3/62 = 359/372 = 0.965$. The adjusted value of the test statistic is thus $2.82 \times 0.965 = 2.72$. We refer to a Chi-squared distribution on $(1/2) \times 2 \times 3 \times 1 = 3$ degrees of freedom, the upper 5% critical value of which is 7.81. The adjusted test statistic value is much less than this critical value, so we conclude that the two sample covariance matrices could indeed have come from populations with a common dispersion matrix.

In conclusion, however, it is appropriate to make some cautionary comments. A formal significance test has limited value, and a nonsignificant result does not justify the blind acceptance of the null hypothesis. The data should still be examined critically and if necessary transformed or edited by removal of outliers or other dubious points. It should also be remembered that the above test makes the vital assumption of normality of data, so a significant result may be just as much an indication of nonnormality as

2 Covariance Matrices

of heterogeneity of dispersion matrices. The bottom line is that all significance tests should be interpreted critically and with caution.

Covariance Structure Models

Problems with Measuring Constructs

Constructs, represented by **latent variables** in statistical models, abound in scientific theories but they are especially commonplace in social research. Unlike fundamental properties such as length, mass, or time, measuring a construct is, however, difficult. One reason is that constructs, such as ‘mathematics ability’ in educational research or ‘consumer confidence’ in economics, are not directly observable, and only their indicators are available in practice. Consequently, a teacher may gauge a pupil’s mathematics ability only indirectly through, for example, the pupil’s performance on a pencil and paper test of mathematics, or from the pupil’s returned homework assignments. In economics, consumer confidence is discussed frequently in terms of what is observable about spending behavior such as actual tallies of sales receipts, or plans for major purchases in the near term.

Furthermore, indicators are imperfect measures of a construct. First, different indicators tap nonoverlapping aspects of the hypothesized construct. Researchers thus need to consider more than a few indicators to represent, by triangulation, the construct more completely. The teacher in our example should therefore thoughtfully balance test results with homework grades, and perhaps other pertinent sources of information as well, when evaluating a pupil’s ability. The economist surveys a broad mix of consumer spending attitudes and behaviors in tracking consumer confidence. Second, an indicator may contain information specific to itself but which is unrelated to the construct in question. Returning to our classroom assessment example above, while both the test score and performance on homework assignments provide corroborative evidence of mathematics ability, they are clearly two different forms of assessments and thus may each exert their own influence on the outcome. It is quite plausible, for example, that test scores were depressed for some students because the test was completed under time pressure, while the same students were not impacted in a similar way in their homework assignments.

The issues become considerably more challenging when we move from measuring a single construct to understanding the relationships among several constructs. Consider the enduring interest in psychology and education of measuring individual traits and behaviors using multiple items, or multiple tests, in a test battery for the purposes of validating constructs. If individual tests, subtests, or test-lets assembled in a test battery intended for gauging subject matter mastery are affected by incidental features such as presentation or response format, it is clearly critical for establishing the veracity of the test battery that we separate out information that is peculiar to presentation and response formats from information pertaining to subject matter. Elsewhere, research on halo effects, test form factors, and response sets reflects concern for essentially the same set of analytic issues.

Covariance Structure Model

A systematic assessment of the relative impact of known or hypothesized item or test features on the subject’s performance may be facilitated, first, by comparing within the respondent item or test effects using experimental design principles (e.g., [10]), a suggestion which Bock [1] attributes to **Sir Cyril Burt** [4]. Guilford’s [7] study of the structure of the intellect analyzed subject responses to an incomplete cross-classification of test items. Another prominent example of this approach to understanding measures is the classic attempt of Campbell and Fiske [5] to detect method bias in a test validation study by examining the sample correlation matrix for a set of tests of several traits assessed by alternative methods in a crossed factorial design. Second, an adequately justified statistical evaluation of the data from such designs is needed in place of the rudimentary comparisons of variances and covariances typified, for example, by the suggestions offered in [5] for exploring their ‘multitrait–multimethod’ matrix (*see also* [24] and **Multitrait–Multimethod Analyses**).

Covariance structure analysis, originally introduced by Bock [1] and elaborated in Bock and Bargmann [2], is a statistical method for the structural analysis of the sample variance-covariance matrix of respondent scores on a test battery aimed at

2 Covariance Structure Models

understanding the make-up of the battery. Covariance structure analysis is based on the familiar linear model

$$\mathbf{y}_i = \boldsymbol{\mu} + \mathbf{A}\boldsymbol{\xi}_i + \boldsymbol{\varepsilon}_i \quad (1)$$

for a set of p continuous measures, $\mathbf{y}_i$, observed for a sample of subjects $i = 1, 2, \dots, N$ drawn randomly from a single population.

Considering each term in model (1) in turn, $\boldsymbol{\mu}$ is the population mean, a quantity that is typically ignored for analyses with arbitrary measurement scales. A notable exception arises of course in studies involving repeated measurements, in which case it is meaningful to compare scores from p different administrations of the same test. $\boldsymbol{\xi}_i$ is the $m \times 1$ vector of latent scores for subject i , which is assumed to be distributed multinormal as $N_m(\mathbf{0}, \boldsymbol{\Phi})$. They locate each subject in the latent space spanned presumably by the m constructs. $\mathbf{A}$ is a $p \times m$, for $m \leq p$, matrix of known constants of rank $\ell \leq m$. Each element, a_{jk} , indicates the contribution of the k th latent component ($k = 1, 2, \dots, m$) to the j th observed measure ($j = 1, 2, \dots, p$). $\boldsymbol{\varepsilon}_i$ is the $p \times 1$ vector for subject i representing measurement error and is also assumed to be distributed multinormal as $N_p(\mathbf{0}, \boldsymbol{\Psi})$. Under these assumptions, and conditional on $\boldsymbol{\xi}_i$, $\mathbf{y}_i$ is multinormal with population mean $\boldsymbol{\mu}$ and population variance-covariance matrix

$$\boldsymbol{\Sigma} = \mathbf{A}\boldsymbol{\Phi}\mathbf{A}' + \boldsymbol{\Psi}. \quad (2)$$

In cases where $\mathbf{A}$ is rank-deficient (i.e., $\ell < m$), only ℓ linearly independent combinations of the m latent variables, $\boldsymbol{\xi}_i$, are estimable. Bock and Bargmann [2] suggested a reparameterization that takes $\boldsymbol{\xi}_i$ into $\boldsymbol{\theta}_i$ ($\ell \times 1$), by choosing a set of ℓ linear contrasts $\mathbf{L}$ ($\ell \times m$) such that $\boldsymbol{\theta}_i = \mathbf{L}\boldsymbol{\xi}_i$. Given any choice for $\mathbf{L}$, model (1) is then

$$\mathbf{y}_i = \boldsymbol{\mu} + \mathbf{K}\boldsymbol{\theta}_i + \boldsymbol{\varepsilon}_i, \quad (3)$$

from setting $\mathbf{A}\boldsymbol{\xi}_i = \mathbf{K}\mathbf{L}\boldsymbol{\xi}_i = \mathbf{K}\boldsymbol{\theta}_i$ and solving $\mathbf{K} = \mathbf{A}\mathbf{L}'(\mathbf{L}\mathbf{L}')^{-1}$. Writing the variance-covariance matrix of $\boldsymbol{\theta}_i$ as $\boldsymbol{\Phi}^* = \mathbf{L}\boldsymbol{\Phi}\mathbf{L}'$, the population variance-covariance matrix for a given $\mathbf{L}$ is $\boldsymbol{\Sigma} = \mathbf{K}\boldsymbol{\Phi}^*\mathbf{K}' + \boldsymbol{\Psi}$. Jöreskog [9] noted that reparameterization in rank-deficient cases is an alternative to imposing equality constraints on $\boldsymbol{\Phi}$ where reasonable.

Specific Covariance Models

From (1) and (2), it is clear that the covariance structure model is a **confirmatory factory model** with known factory loadings [2]. Covariance structure analysis focuses on estimating and testing *a priori* hypotheses induced by $\mathbf{A}$ on the variance-covariance matrix of the latent variables, $\boldsymbol{\Phi}$, under alternative specifications of both $\boldsymbol{\Phi}$ and the measurement error components represented by $\boldsymbol{\Psi}$. In Bock [1] and Bock and Bargmann [2], these covariance matrices are uncorrelated, but they may be either homogeneous or heterogeneous. In a specification designated as Case I in Bock and Bargmann [2] the latent variables are uncorrelated and the error are uncorrelated and homogeneous, that is, $\boldsymbol{\Phi} = (\varphi_1^2, \varphi_2^2, \dots, \varphi_k^2, \dots, \varphi_m^2)$ and $\boldsymbol{\Psi} = \psi^2\mathbf{I}$. A special Case I model occurs when all the items in a battery tap a single latent variable, leading to the so-called ‘true-score’ model with compound symmetry ($\mathbf{A} = \mathbf{1}$, $\boldsymbol{\Phi} = \phi^2\mathbf{I}$, $\boldsymbol{\Psi} = \psi^2\mathbf{I}$) with population variance-covariance matrix $\boldsymbol{\Sigma} = \phi^2\mathbf{1}\mathbf{1}' + \psi^2\mathbf{I}$. A Case II covariance structure model covers applications in which the latent variables are uncorrelated and the errors are uncorrelated but are heterogeneous, that is, $\boldsymbol{\Psi} = (\psi_1^2, \psi_2^2, \dots, \psi_j^2, \dots, \psi_p^2)$.

In a Case III model, the latent variables are uncorrelated and the errors are also uncorrelated and homogeneous as in Case I, but only after scale differences are removed. Case III assumptions lead to a generalization of model (1) in which the population variance-covariance matrix takes the form

$$\boldsymbol{\Sigma} = \boldsymbol{\Gamma}(\mathbf{A}\boldsymbol{\Phi}\mathbf{A}' + \boldsymbol{\Psi})\boldsymbol{\Gamma}, \quad (4)$$

for the diagonal matrix of unknown scaling constants, $\boldsymbol{\Gamma}$. Models with scale factors may be important in social research because, as noted above, measurement scales are most often arbitrary. In practice, however, achieving identifiability requires fixing one of the unknown scaling coefficients to an arbitrary constant, or by setting $\boldsymbol{\Psi} = \psi^2\mathbf{I}$ [22].

Note that other forms for $\boldsymbol{\Phi}$ may be plausible but its identification will depend on the available data. Wiley et al. [22] considered a model with correlated factors $\boldsymbol{\xi}_i$ in a study of teaching practices which we will reexamine below.

Estimation and Testing

Given the population variance-covariance matrix (4) and its sample estimate $\mathbf{S}$, Bock and Bargmann [2]

provided a **maximum likelihood** solution based on the log-likelihood

$$\ln L = -\frac{Np}{2} \ln(2\pi) - \frac{N}{2} \ln |\Sigma| + N \ln |\Gamma^{-1}| - \frac{N}{2} \text{tr}(\Sigma^{-1} \Gamma^{-1} S \Gamma^{-1}). \quad (5)$$

It is clear from our discussion above that a covariance structure model belongs to the broader class of **structural equation models** (SEM). Consequently, widely available programs for SEM analyses, such as AMOS, EQS, LISREL, MPLUS, and SAS PROC CALIS (*see Structural Equation Modeling: Software*), will routinely provide the necessary estimates, standard errors, and a host of fit statistics for fitting covariance structure models.

A Study of Teaching Practices

Wiley, Schmidt, and Bramble [22] examined data from [17], consisting of responses from 51 students to a test with items sharing combinations of three factors thought to influence classroom learning situations and teaching practices (see Table 1). The study sought to compare conditions in first and sixth grade classrooms, teaching styles that were deemed teacher-centered as opposed to pupil-centered, and teaching methods that were focused on drill as opposed to promoting discovery. The eight subtests comprised a 2^3 factorial design.

Following Wiley, Schmidt, and Bramble [22], we parameterize an overall latent component, a contrast between grade levels, a contrast between teaching styles, and teaching methods represented seriatim by

the four columns in design matrix

$$\mathbf{A} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & -1 \\ 1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \\ 1 & -1 & -1 & -1 \end{bmatrix}. \quad (6)$$

Results from SAS PROC CALIS support [22] conclusion that a model with correlated latent components estimated by

$$\hat{\Phi} = \begin{bmatrix} 9.14 (1.92) & & & \\ 0.73 (0.48) & 0.68 (0.23) & & \\ 0.63 (0.42) & -0.06(0.15) & 0.43 (0.19) & \\ -0.61(1.05) & -0.51(0.37) & 1.13 (0.35) & 5.25 (1.14) \end{bmatrix} \quad (7)$$

and heterogeneous error variances estimated by $\hat{\Psi} = \text{diag}[1.63 (0.90), 5.10 (1.40), 8.17 (1.90), 5.50 (1.56), 1.93 (0.91), 2.33 (0.84), 5.79 (1.44), 2.55 (0.93)]$ indicated an acceptable model fit ($\chi^2_{18} = 25.24$, $p = 0.12$; CFI = 0.98; RMSEA = 0.09) superior to several combinations of alternative forms for Φ and Ψ .

In comparing the relative impact of the various factors in teachers' judgments on conditions that facilitated student learning, Wiley et al. [22, p. 322], however, concluded erroneously that teaching style did not affect teacher evaluations due, most likely, to a clerical error in reporting 0.91 as the standard error estimate for $\hat{\phi}_3^2 = 0.43$ instead of 0.19. The results therefore suggested that, on the contrary, both teaching practices influenced the performance of subjects. Of particular interest to research on teaching, the high

Table 1 Miller–Lutz sample variance–covariance matrix

Grade	Style	Method								
1	Teacher	Drill	18.74							
1	Teacher	Discovery	9.28	18.80						
1	Pupil	Drill	15.51	7.32	21.93					
1	Pupil	Discovery	3.98	15.27	4.10	26.62				
6	Teacher	Drill	15.94	4.58	13.79	−2.63	19.82			
6	Teacher	Discovery	7.15	13.63	3.86	15.33	3.65	16.81

4 Covariance Structure Models

positive correlation between teacher approach and teacher method ($\hat{\rho}_{34} = 0.75$) suggested that combining a teacher-centered approach with drill produced dramatically different responses among subjects when compared with subjects engaged in pupil-centered discovery.

Relationships with Other Models

Covariance structure analysis generalizes the conventional mixed-effects model for a design with one random way of classification (subjects or respondents) and a possibly incomplete fixed classification (tests) by providing tests for a more flexible variance-covariance structure. As a statistical model, its application extends beyond the immediate context of tests and testing to include all problems in which the design on the observed measures is known.

For some applications, the matrix of coefficients $\mathbf{A}$ may be structured in a way to produce a hypothesized covariance matrix for the latent variables. For example,

$$\mathbf{A} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 \end{bmatrix} \quad (8)$$

induces the Guttman's [8] simplex pattern with correlation $\rho^{|j-j'|}$ among a set of $p = 4$ ordered tests ($j = 1, 2, \dots, p; j' = 1, 2, \dots, p$).

Agreement between results from a covariance structure analysis and Generalizability theory should not be surprising when the models considered are equivalent (see, for example, the excellent review by Linn and Werts [11]). As an example, Marcoulides [14] considered the flexibility of a covariance structure analysis for Generalizability analysis (see **Generalizability**), with an illustration involving four job analysts who each provided job satisfaction ratings on 27 described occupations on two occasions. This application employed a design with a random way of classification (job descriptions) and a crossed-classification of raters and occasions. The proposed

model with

$$\mathbf{A} = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 & 1 \end{bmatrix}, \quad \Phi = \begin{bmatrix} \varphi_1^2 & & & & & & \\ & \varphi_2^2 & & & & & \\ & & \varphi_2^2 & & & & \\ & & & \varphi_2^2 & & & \\ & & & & \varphi_2^2 & & \\ & & & & & \varphi_3^2 & \\ & & & & & & \varphi_3^2 \end{bmatrix} \quad (9)$$

and $\Psi = \psi^2 \mathbf{I}$, estimated an overall variance among job categories (φ_1^2), constrained variability to be equal among raters (φ_2^2), constrained variability between the two occasions (φ_3^2) to be equal, and assumed that error variances to be homogeneous (ψ^2). Estimation and model comparison results via maximum likelihood using many of the software available for fitting SEMs gave results comparable to the more usual Analysis of Variance (ANOVA) solution (see [3, 19]).

Willett and Sayer [23], reviewing the work of McArdle and Epstein [15] and Meredith and Tisak [16], noted that mixed-effects models for growth are implicit in covariance structure analysis of complete repeated measurement designs. SEM software provided the overarching modeling framework for balanced growth data: A conventional growth model is estimated when the design on time is known, but when some coefficients of the design matrix for growth are unknown, a latent curve model is considered.

This reading is of course consistent with earlier attempts within the SEM literature to extend the applications to multilevel multivariate data (e.g., [6, 13, 18] and **Structural Equation Modeling: Multilevel**). Note that the models considered in Bock [1], Bock and Bargmann [2], Wiley, Schmidt, and Bramble [22] dealt with the covariance structure for multivariate outcomes of unreplicated sampled units. If replications for subjects are present and the replications are small and equal (balanced), covariance structure models need no modification because replications may be treated as part of a subject's

single observation vector. However, when replications within subjects are unbalanced, that is, for each subject i we observed a $n_i \times p$ matrix $\mathbf{Y}_i = [\mathbf{y}'_{i1}, \mathbf{y}'_{i2}, \dots, \mathbf{y}'_{ir}, \dots, \mathbf{y}'_{in_i}]$, the covariance structure model (1) takes the extended form of a multivariate mixed-effects model

$$\mathbf{Y}_i = \mathbf{\Xi}_i \mathbf{A} + \mathbf{E}_i \quad (10)$$

treated, for example, in Thum [20, 21] in Littell, Milliken, Stroup, and Wolfinger [12], and in more recent revisions of SEM and multilevel frameworks (see **Generalized Linear Mixed Models**).

Covariance/variance/correlation

The covariance is a ‘uniting concept’ in statistics, yet is often neglected in undergraduate and graduate statistics courses. The variance and correlation, which are much more popular statistical indices, are each a special case of the covariance. **Structural equation modeling** (SEM) is the statistical method in which these three measures are most completely respected and accounted for. The current entry will describe each index in a common framework that allows their interrelationships to be apparent. Following separate treatment, a formula will be presented that explicitly shows the relationships between these three indices. Finally, the role of each in SEM will be described.

Hays [1] defines the covariance, an indicator of the relationship between two variables, as a measure of ‘departure from independence of X and Y ’. When X and Y are independent, the covariance is zero. To the extent that they are not independent, the covariance will be different from zero. If the two variables are positively related, the covariance will be positive; an inverse relationship between X and Y will result in a negative covariance. However, the covariance is sensitive to the scale of measurement of the two variables – that is, variables with large variance will have more extreme covariance values than variables with small variance – which makes the magnitude of the covariance difficult to interpret across different measurement settings. The covariance is, however, defined on centered variable values; that is, the means are subtracted from each score as they enter the covariance formula, and the resulting transformed scores are guaranteed to each have a mean of zero. In this sense, the covariance equates the means of the two variables.

It is exactly this feature of the covariance – the fact that its bounds depend on the variance of X and Y – that can be used to transform the covariance into the correlation. The correlation is often referred to informally as a ‘standardized covariance’. One of the many ways it can be defined is by computing the covariance, then dividing by the product of the two standard deviations. This adjustment rescales the covariance into an index – Pearson’s product-moment correlation coefficient – that is guaranteed to range between -1 and $+1$. The transformation results

in new variables that have their variability equated to one another, and equal to one (which means the variance and standard deviation of each variable become identical). But it is important to note that the more well-behaved measure – the correlation – no longer contains any information about either the mean or the variance of the original variables.

It is of conceptual value to note that an even broader measure than the covariance exists, in which the raw moments are defined by simply multiplying the raw scores for each X and Y value, summing them, and dividing by a function of the sample size. This measure is sensitive to both the mean and the variance of each of the two variables. The covariance, on the other hand, is sensitive only to the variance of each of the two variables. The correlation is not sensitive to either the mean or the variance. This gives the correlation the advantage of being invariant under linear transformation of either of the raw variables, because linear transformation will always return the variable to the same standardized value (often called the *z-score*). It also gives it the disadvantage that no information about either the means or the variances is accounted for within the correlational formula.

The variance is the simplest of these concepts, because it applies to a single variable (whereas the other two concepts are bivariate by definition). Other entries in this encyclopedia describe the details of how the variance is defined, so we will not develop computational details but rather will discuss it conceptually. The variance – referred to by mathematical statisticians as a function of the ‘second moment about the mean’ – measures the average deviation of each score from the mean, in squared units of the variable’s scale of measurement. The variance is often unsquared to rescale it into units interpretable in relation to the original scale, and this unsquared variance measure is called the *standard deviation*. Certain properties of the variance are of particular importance within statistics. First, the variance has an important least squares property. Because the squared deviations are defined about the mean, this computation is guaranteed to give the minimum value compared to using other measures (constants) within the formula. This optimality feature helps place the variance within normal theory, maximum likelihood estimation, and other topics in statistics. However, the variance is also highly sensitive to outliers, because the deviations from the mean are squared (and therefore magnified) within the variance formula. This concern

often leads applied statisticians to use more robust measures of variability, such as the **median absolute deviation** (MAD) statistic. Whereas the mean minimizes the sum of squared deviations compared to any other constant, the median has the same optimality property in the context of absolute deviations.

The variance, like the correlation, is a special case of the covariance – it is the covariance of a variable with itself. The variance is zero if and only if all the scores are the same; in this case, the variable can be viewed as ‘independent of itself’ in a sense. Although covariances may be positive or negative – depending on the relation between the two variables – a variable can only have a positive relationship with itself, implying that negative variances do not exist, at least computationally. Occasionally, estimation routines can estimate negative variances (in **factor analysis**, these have a special name – Heywood Cases). These can result from missing data patterns or from lack of fit of the model to the data.

The formula given in Hays to compute the covariance is $\text{cov}(X, Y) = E(XY) - E(X)E(Y)$, which shows that the covariance measures the departure from independence of X and Y . A straightforward computational formula for the covariance shows the relationships between the three measures, the covariance, the correlation, and variance:

$$\text{cov}(X, Y) = r_{XY}s_Xs_Y. \quad (1)$$

Note that this computational formula may take slightly different forms, depending on whether the unbiased estimates or the sample statistics are used – the formula above gives the most straightforward conceptual statement of the relationship between

these three statistics. Dividing this formula through by the product of the standard deviations shows how the correlation can be obtained by standardizing the covariance (i.e., by dividing the covariance by the product of the standard deviations).

In structural equations (SEM) models (and factor analysis to a lesser extent), appreciating all three of these important statistical indices is prerequisite to understanding the theory and to being able to apply the method. Most software packages that estimate SEM models can fit a model to either covariances or to correlations – that is, these packages define predicted covariance or correlation matrices between all pairs of variables, and compare them to the observed values from real data (*see **Structural Equation Modeling: Software***). If the model is a good one, one or more of the several popular fit statistics will indicate a good match between the observed and predicted values. With a structural equation model, observed or latent variables can be linked to another observed or latent variable either through a correlation or covariance, and can also be linked back to itself through a variance. These variances may be constrained to be equal to one – implying standardized variables – or unconstrained – implying unstandardized variables. The covariances/correlations can be estimated, constrained, or fixed.

Cox, Gertrude Mary

Born: January 13, 1900, in Dayton, USA.

Died: October 17, 1978, in Durham, USA.

Gertrude Cox was born in the American Midwest and grew up with a strong commitment to social services. She intended to become a deaconess in the Methodist Episcopal Church, but then decided that she would prefer to follow academic pursuits. She graduated from Iowa State College in 1929 with a degree in mathematics.

After graduation, Cox stayed on at Iowa State College (now Iowa State University) to earn a master's degree in statistics under the direction of **George Snedecor**. This was the first master's degree in statistics at that institution, but far from the last.

Cox went on to the University of California at Berkeley to work on her Ph. D., but left without her degree to return to Iowa State to direct the Computing Laboratory under George Snedecor. In fact, she never did finish her Ph.D., although she was appointed an Assistant Professor of Statistics at Iowa.

In 1940, George Snedecor was asked to recommend names to chair the new Department of Experimental Statistics at North Carolina State University at Raleigh. Gertrude Cox was appointed to this position with the title of Professor of Statistics. From that time until her retirement, her efforts were devoted to building and strengthening the role of statistics in the major university centers in North Carolina.

In 1944, North Carolina established an all-University Institute of Statistics, and Gertrude Cox was selected to head it. The next year, she obtained funds to establish a graduate program in statistics at North Carolina State, and the following year, she obtained additional funds to establish a Department of Mathematical Statistics at the University of North Carolina at Chapel Hill. Not content with that, she went on to find further funding to establish the Department of Biostatistics at UNC, Chapel Hill in 1949. These departments now offer some of the best-known programs in statistics in the United States.

One of her major interests was experimental design, and she had been collecting material for a book on design since her early days at Iowa. As R. L. Anderson [1] has pointed out, Cox believed very strongly in the role of **randomization in experimental design** and in the need to estimate **power**.

In 1950, Gertrude Cox and **William Cochran** published the classic Cochran and Cox: *Experimental Design* [3].

Though she never completed her Ph. D., Iowa State bestowed on her an honorary Doctorate of Science in 1958, in recognition of the major contributions she made to her field.

In this same year, Cox and others from North Carolina State began work to create a Statistics Division within what is now Research Triangle Park, a cooperative arrangement between the universities in Raleigh, Durham, and Chapel Hill. Not surprisingly, Gertrude Cox was asked to head that division, and she retired from North Carolina State in 1960 for that purpose. She retired from the division position in 1964.

Aside from her academic responsibilities, Gertrude Cox was President of the American Statistical Association in 1956. In addition, she served as the first editor of *Biometrics* and was the president of the International Biometric Society in 1968–69. In 1975, she was elected to the National Academy of Sciences. It is worth noting that in addition to herself, four of the faculty that she hired at North Carolina were also elected to the National Academy of Sciences (Bose, Cochran, Hoeffding, and **Hotelling**) [2].

Following her retirement in 1965, Cox served as a consultant to promote statistical activities in Thailand and Egypt. In 1989, the American Statistical Association Committee on Women in Statistics and the Women's Caucus in Statistics established the Gertrude M. Cox Scholarship. It is presented annually to encourage more women to enter statistics, and has become a prestigious award.

Gertrude Cox contracted leukemia and died in 1978.

Cramér–von Mises Test

Let $(x_1, x_2, \dots, x_n)$ and $(y_1, y_2, \dots, y_m)$ be independent random samples from distributions with cumulative distribution functions $F(z)$ and $G(z)$, respectively. The existence of cumulative distribution functions (cdfs) implies that the scale of measurement of the random variables X and Y is at least ordinal: $F(z)$ is the probability that the random variable X takes a value less than or equal to z and thus increases from zero to one as the value of z increases.

The hypothesis to be nullified is that $F(z) = G(z)$ for all values of z . The alternative hypothesis is that the two cdfs differ for one or more values of z . The Cramér–von Mises test is not a test of equivalence of means or variances, but a test of equivalence of distributions. The test is inherently nondirectional.

Let $F^*(z)$ and $G^*(z)$ be the empirical (cumulative) distribution functions based on the samples $(x_1, x_2, \dots, x_n)$ and $(y_1, y_2, \dots, y_m)$ respectively. That is, $F^*(z)$ is the proportion of values in the sample $(x_1, x_2, \dots, x_n)$ that are less than or equal to z and $G^*(z)$ is the proportion of values in the sample $(y_1, y_2, \dots, y_m)$ that are less than or equal to z .

The test statistic is

$$T = k\{\sum_{j=1,2,\dots,n}[F^*(x_j) - G^*(x_j)]^2 + \sum_{j=1,2,\dots,m}[F^*(y_j) - G^*(y_j)]^2\} \quad (1)$$

where

$$k = \frac{mn}{(m+n)^2}. \quad (2)$$

The squared difference between the two empirical cdfs is evaluated at each of the $(m+n)$ values in the

combined samples. If the sum of these squared differences is large, the hypothesis of equal distributions can be nullified.

The exact null distribution of T can be found by permuting the purported sources of the observed $(m+n)$ values in all possible ways, n from random variable X and m from random variable Y , and then computing $F^*(z)$, $G^*(z)$, and T from each permutation. Where m and n are too large to make this feasible, an adequate Monte Carlo (*see Monte Carlo Simulation*) approximation to the null distribution can be created by randomly sampling the potential permutations a very large number of times, for example, 5000. An asymptotic null distribution, valid for large samples from continuous random variables, has been developed [1] and relevant tail probabilities are provided in [2].

There is a one-sample goodness-of-fit version of the Cramér–von Mises test in which a known probability distribution, for example, the normal, replaces $G^*(z)$. Both Cramér–von Mises tests are dominated in usage by the one- and two-sample **Kolmogorov–Smirnov** or Smirnov tests.

Criterion-Referenced Assessment

Criterion-referenced testing (CRT) was introduced in the United States in the 1960s as a response to the need for assessments that could determine what persons knew and could do in relation to a well-defined domain of knowledge and skills, rather than in relation to other persons [3, 15]. With the CRT score information, the level of proficiency of candidates can be determined, and in many cases, diagnostic information can be provided that will be helpful to candidates in working on their weaknesses. Today, the uses of CRTs are widespread in education, the military, and industry [9]. What follows first in the entry, is a brief description of the differences between norm-referenced tests (NRTs) and CRTs. It is because of the fundamental differences that a number of challenges have arisen regarding CRTs – standard-setting and estimating reliability, to name two, and it is these technical challenges that are the focus of this entry. NRTs, on the other hand, have received extensive research and development over the years, and from a technical perspective, there are few remaining challenges to overcome for their effective use.

Differences Between Norm-referenced and Criterion-referenced Tests

Criterion-referenced tests and norm-referenced tests serve different purposes and these differences have implications for test development and evaluation. Norm-referenced tests are primarily intended to distinguish or compare examinees on the construct measured by the test. Examinees are basically rank-ordered based on their test scores. For the rank ordering to be reliable, the test itself needs to spread out the examinees so that the always-present measurement errors do not distort too much the ranking that would be obtained if true scores had been used. This means that a good norm-referenced test will spread out the examinee scores, and to do that, items of middle difficulty and high discriminating power are usually best – test score variability needs to be maximized to the extent possible, given constraints on such things as test content and test length. Test score

reliability is judged by the stability of the examinee rankings or scores over parallel-form administrations or test-retest administrations of the test. Proxies for the double administration of the test or administration of parallel forms of the test come from single-administration reliability estimates such as corrected split-half and internal consistency estimates (i.e., correlation between scores derived from two halves of a test, and then adjusting the correlation upward by the Spearman–Brown formula to predict the reliability of the full-length test; or coefficient alpha for polytomous response data, and the KR-20 and KR-21 formulas for binary data). Validity is established by how well the scores serve their intended purpose. The evidence might come from criterion-related or construct validity studies (*see Validity Theory and Applications*).

CRTs, on the other hand, are intended to indicate an examinee's level of proficiency in relation to a well-defined domain of content. Usually scores are interpreted in relation to a set of performance standards that are set on the test score reporting scale. Primary focus in item selection is not on the item statistics as it is when building an NRT, though they are of concern (for example, items with negative point biserial correlations would never be selected), but rather primary focus in item selection is on the content match of items to the content domain being measured by the test. Test items are needed that insure the content validity of the test and so content is a primary consideration in item selection. That there may be limited score variability in the population of examinees is not of any significance, since examinee scores, independent of other examinees, are compared to the content domain covered by the test, and the performance standards in place for test score interpretation and test score uses.

Today with many state criterion-referenced tests, examinees, based upon their test scores, are assigned to one of four performance levels: Failing, Basic, Proficient, and Advanced. Performance standards are the points on the reporting scale that are used to sort examinees into the performance levels. For criterion-referenced credentialing exams, normally only two performance levels are used: passing and failing. Reliability is established, not by correlational statistics as is the case with NRTs, but rather by assessing the consistency of performance classifications of examinees over retests and parallel forms. Proxies for the concept of decision consistency estimated

from single administrations are also possible and will be discussed later in this entry. Validity is typically assessed by how well the test items measure the content domain to which the test scores are referenced. Validity also depends on the performance standards that are set for sorting candidates into performance categories. If they are set improperly (perhaps set too high or too low because of a political agenda of those panelists who set them), then examinees will be misclassified (relative to how they would be classified if true scores were available, and a valid set of performance standards were in place), and the validity of the resulting performance classifications is reduced.

What is unique about CRTs is the central focus on the content measured by the test, and subsequently, on how the performance standards are set, and the levels of decision consistency and accuracy of the resulting examinee classifications. These technical problems will be addressed next.

Setting Performance Standards

Setting performance standards on CRTs has always been problematic (see [1]) because substantial judgment is involved in preparing a process for setting them, and no agreement exists in the field about the best choice of methods (see **Setting Performance Standards: Issues, Methods**). One instructor may be acceptable to set performance standards on a classroom test (consequences are usually low for students, and the instructor is normally the most qualified person to set the performance standards), but when the stakes for the testing get higher (e.g., deciding who will receive a high school diploma, or a certificate to practice in a profession), multiple judges or panelists will be needed to defend the resulting performance standards. Of course, with multiple panelists and each with their own opinion, the challenge is to put them through a process that will converge on a defensible set of performance standards. In some cases, even two or more randomly equivalent panels are set up so that the replicability of the performance standards can be checked. Even multiple panels may not appease the critics: The composition of the panel or panels, and the number of panel members can become a basis for criticism.

Setting valid performance standards involves many steps (see [4]): Choosing the composition of the panel or panels and selecting a representative sample of

panel members, preparing clear descriptions of the performance levels, developing clear and straightforward materials for panels to use in the process, choosing a standard-setting method that is appropriate for the characteristics of the test itself and the panel itself (for example, some methods can only be used with multiple-choice test items, and other methods require item statistics), insuring effective training (normally, this is best accomplished with field testing in advance of the actual standard-setting process), allowing sufficient time for panels to complete their ratings and participate in discussions and revising their ratings (this activity is not always part of a standard-setting process), compiling the panelists' ratings and deriving the performance standards, collecting validity data from the panelists, analyzing the available data, and documenting the process itself.

Counting variations, there are probably over 100 methods for setting performance standards [1]. Most of the methods involve panelists making judgments about the items in the test. For example, with the Angoff method, panelists predict the expected performance of borderline candidates at the Basic cut score, the Proficient cut score, and at the Advanced cut score, on all of the items on the test. These expected item scores at a cut score are summed to arrive at a panelist cut score, and then averaged across panelists to arrive at an initial cut score for the panel. This process is repeated to arrive at each of the cut scores. Normally, discussion follows, and then panelists have an opportunity to revise their ratings, and then the cut scores are recalculated. Sometime during the process panelists may be given some item statistics, or consequences of particular cut scores that they have set (e.g., with a particular cut score, 20% of the candidates will fail). This is known as the Angoff method.

In another approach to setting performance standards, persons who know the candidates (called 'reviewers') and who know the purpose of the test might be asked to sort candidates into four performance categories: Failing, Basic, Proficient, and Advanced. A cut score to distinguish Failing from Basic on the test is determined by looking at the actual test score distributions of candidates who were assigned to either the Failing or Basic categories by reviewers. A cut score is chosen to maximize the consistency of the classifications between candidates based on the test and the reviewers. The process is then repeated for the other cut scores. This is known

as the contrasting groups method. Sometimes, other criteria for placing cut scores might be used, such as doubling the importance of minimizing one type of classification error (e.g., false positive errors) over another (e.g., false negative errors).

Many more methods exist in the measurement literature: Angoff, Ebel, Nedelsky, contrasting groups, borderline group, book-mark, booklet classification, and so on. See [1] and [5] for complete descriptions of many of the current methods.

Assessing Decision Consistency and Accuracy

Reliability of test scores refers to the consistency of test scores over time, over parallel forms, or over items within the test. It follows naturally from this definition that calculation of reliability indices would require a single group of examinees taking two forms of a test or even a single test a second time, but this is often not realistic in practice. Thus, it is routine to report single-administration reliability estimates such as corrected split-half reliability estimates and/or coefficient alpha. Accuracy of test scores is another important concern that is often checked by comparing test scores against a criterion score, and this constitutes a main aspect of validity [8].

With CRTs, examinee performance is typically reported in performance categories and so reliability and the validity of the examinee classifications are of greater importance than the reliability and validity associated with test scores. That is, the consistency and accuracy of the decisions based on the test scores outweighs the consistency and the accuracy of test scores with CRTs.

As noted by Hambleton and Slater [7], before 1973, it was common to report a KR-20 or a corrected split-half reliability estimate to support the use of a credentialing examination. Since these two indices only provide estimates of the internal consistency of examination scores, Hambleton and Novick [6] introduced the concept of the consistency of decisions based on test scores, and suggested that the reliability of classification decisions should be defined in terms of the consistency of examinee decisions resulting from two administrations of the same test or parallel forms of the test, that is, an index of reliability which reflects the consistency of classifications across repeated testing. As compared with the definition of

decision consistency (DC) given by Hambleton and Novick [6], decision accuracy (DA) is the ‘extent to which the actual classifications of the test takers agree with those that would be made on the basis of their true scores, if their true scores could somehow be known’ [12].

Methods of Estimating DC and DA

The introduction of the definition of DC by Hambleton and Novick [6] pointed to a new direction for evaluating the reliability of CRT scores. The focus was to be on the reliability of the classifications or decisions rather than on the scores themselves. Swaminathan, Hambleton, and Algina [19] extended the Hambleton–Novick concept of decision consistency to the case where there were not just two performance categories:

$$p_0 = \sum_{i=1}^k p_{ii} \quad (1)$$

where p_{ii} is the proportion of examinees consistently assigned to the i -th performance category across two administrations, and k is the number of performance categories. In order to correct for chance agreement, based on the kappa coefficient (*see Rater Agreement – Kappa*) by Cohen [2], which is a generalized proportion agreement index frequently used to estimate inter-judge agreement, Swaminathan, Hambleton, and Algina [20] put forward the kappa statistic which is defined by:

$$\kappa = \frac{p - p_c}{1 - p_c} \quad (2)$$

where p is the proportion of examinees classified in the same categories across administrations, and p_c is the agreement expected by chance factors alone.

The concepts of decision consistency and kappa were quickly accepted by the measurement field for use with CRTs, but the restriction of a double administration was impractical. A number of researchers introduced single-administration estimates of decision consistency and kappa, analogous to the corrected split-half reliability that was often the choice of researchers working with NRTs. Huynh [11] put forward his two-parameter ‘bivariate beta-binomial model’. His model relies on the assumption that a group of examinees’ ability scores follow the beta

4 Criterion-Referenced Assessment

distribution with parameters α and β , and the frequency of the observed test scores x follow the beta-binomial (or negative hypergeometric) distribution with parameters α and β . The model is defined by the following:

$$f(x) = \frac{n!}{x!(n-x)!} \frac{B(\alpha+x, \alpha+\beta-x)}{B(\alpha, \beta)} \quad (3)$$

where n is the total number of items in the test, and B is the beta function with parameters α and β , which can be estimated either with the moment method – making use of the first two moments of the observed test scores – or with the **maximum likelihood (ML)** method described in his paper. The probability that an examinee has been consistently classified into a particular category can then be calculated by using the beta-binomial density function. Hanson and Brennan [10] extended Huynh's approach by using the four-parameter beta distribution for true scores.

Subkoviak's method [18] is based on the assumptions that observed scores are independent and distributed binomially, with two parameters – the number of items and the examinee's proportion-correct true score. His procedure estimates the true score for each individual examinee without making any distributional assumptions for true scores. When combined with the binomial or compound binomial error model, the estimated true score will provide a consistency index for each examinee, and averaging this index over all examinees gives the DC index.

Since the previous methods all deal with binary data, Livingston and Lewis [12] came up with a method that can be used with data including either dichotomous, polytomous, or the combination of the two. It involves estimating the distribution of the proportional true scores T_p using strong true score theory [13]. This theory assumes that the proportional true score distribution has the form of a four-parameter beta distribution with density

$$g\left(\frac{T_p}{\alpha, \beta, a, b}\right) = \frac{1}{Beta(\alpha+1, \beta+1)} \times \frac{(T_p - a)^\alpha (b - T_p)^\beta}{(b - a)^{\alpha+\beta+1}} \quad (4)$$

where $Beta$ is the beta function, and the four parameters of the function can be estimated by using the first four moments of the observed scores for

the group of examinees. Then the conditional distribution of scores on an alternate form (given true score) is estimated using a binomial distribution.

All of the previously described methods operate in the framework of **classical test theory (CTT)**. With the popularization of **item response theory (IRT)**, the evaluation of decision consistency and accuracy under IRT has attracted the interest of researchers. For example, Rudner ([16], [17]) introduced his method for evaluating decision accuracy in the framework of IRT.

Rudner [16] proposed a procedure for computing expected classification accuracy for tests consisting of dichotomous items and later extended the method to tests including polytomous items [17]. It should be noted that Rudner referred to θ and $\hat{\theta}$ as 'true score' and 'observed score' respectively in his papers. He pointed out that because of the fact that for any given true score θ , the corresponding observed score $\hat{\theta}$ is expected to be normally distributed, with a mean θ and a standard deviation of $se(\theta)$, the probability of an examinee with a given true score θ of having an observed score in the interval $[a, b]$ on the theta scale is then given by

$$p(a < \hat{\theta} < b|\theta) = \Phi\left[\frac{b-\theta}{se(\theta)}\right] - \Phi\left[\frac{a-\theta}{se(\theta)}\right], \quad (5)$$

where $\Phi(Z)$ is the cumulative normal distribution function. He noted further that multiplying (5) by the expected proportion of examinees whose true score is θ yields the expected proportion of examinees whose true score is expected to be in the interval $[a, b]$, and summing or integrating over all examinees in interval $[c, d]$ gives us the expected proportion of all examinees that have a true score in $[c, d]$ and an observed score in $[a, b]$. If we are willing to make the assumption that the examinees' true scores (θ) are normally distributed, the expected proportions of all examinees that have a true score in the interval $[c, d]$ and an observed score in the interval $[a, b]$ are given by

$$\sum_{\theta=c}^d P(a < \hat{\theta} < b|\theta) f(\theta) = \sum_{\theta=c}^d \left[\Phi\left[\frac{b-\theta}{se(\theta)}\right] - \Phi\left[\frac{a-\theta}{se(\theta)}\right] \right] \Phi\left(\frac{\theta-\mu}{\delta}\right), \quad (6)$$

where $se(\theta)$ is the reciprocal of the square root of the test information function at θ which is the sum of the item information functions in the test, and $f(\theta)$ is the standard normal density function $\Phi(Z)$ [16]. The problem with this method, of course, is that the normality assumption is usually problematic.

Reporting of DC and DA

Table 1 represents a typical example of how DC of performance classifications is being reported. Each of the diagonal elements represents the proportion of examinees in the total sample who were consistently classified into a certain category on both administrations (with the second one being hypothetical), and summing up all the diagonal elements yields the total DC index.

It is a common practice now to report ‘kappa’ in test manuals to provide information on the degree of agreement in performance classifications after correcting for the agreement due to chance.

Table 1 Grade 4 English language arts decision consistency results

Status on parallel form					
Status on form taken	Failing	Basic	Proficient	Advanced	Total
Failing	0.083	0.030	0.000	0.000	0.113
Basic	0.030	0.262	0.077	0.001	0.369
Proficient	0.000	0.077	0.339	0.042	0.458
Advanced	0.000	0.001	0.042	0.018	0.060
Total	1.00	0.369	0.458	0.060	1.00

Note: From Massachusetts Department of Education [14].

Also reported is the ‘conditional error’, which is the measurement error associated with test scores at each of the performance standards. It is helpful because it indicates the size of the measurement error for examinees close to each performance standard.

The values of DA are usually reported in the same way as in Table 1, only that the cross-tabulation is between ‘true score status’ and the ‘test score status’. Of course, it is highly desirable that test manuals also report other evidence to support the score inferences from a CRT, for example, the evidence of content, criterion-related, and construct and consequential validity.

Appropriate Levels of DC and DA

A complete set of approaches for estimating decision consistency and accuracy are contained in Table 2. Note that the value of DA is higher than that of DC because the calculation of DA involves one set of observed scores and one set of true scores which are supposed to be without any measurement error due to improper sampling test questions, flawed test items, problems with the test administration and so on, while the calculation of DC involves two sets of observed scores.

The levels of DC and DA required in practice will depend on the intended uses of the CRT and the number of performance categories. There have not been any established rules to help determine the levels of decision consistency and accuracy needed for different kinds of educational and psychological assessments. In general, the more important the educational decision to be made, the higher consistency and accuracy need to be.

Table 2 Summary of decision consistency and decision accuracy estimation methods

Critical Region

The basis of null hypothesis testing is a theoretical probability curve representing the theoretical distribution of some statistic (e.g., difference between two means) assuming the independent random selection of two samples from the same population (*see Sampling Distributions*). To decide whether to reject the null hypothesis (the hypothesis that the samples were selected from the same population), one may, following Neyman and Pearson (*see Neyman–Pearson Inference*), establish a criterion value for the statistic and reject the hypothesis if and only if the statistic exceeds that value. All values that exceed that criterion value fall in a region of the decision space that is referred to as the *critical region* (*see Neyman–Pearson Inference*). Conventionally, again following Neyman and Pearson, the decision criterion, α , is selected so as to make the conditional probability of committing a Type I error (rejecting the null hypothesis, given that it is correct) quite small, say .05 or .01.

Suppose, for example, that the question of interest is whether two samples, one with Mean_1 and the other with Mean_2 , can reasonably be assumed to have been randomly drawn from the same population (the null hypothesis), as opposed to having been randomly drawn from different populations, the sample with Mean_2 being drawn from a population

with a larger mean than that of the population from which the sample with Mean_1 was drawn (the alternative hypothesis). A test of the null hypothesis in this case would make use of a theoretical distribution of differences between means of random samples of the appropriate size drawn from the same population. Assuming a strong desire to guard against rejection of the null hypothesis if it is true, the critical region would be defined as a region composed of a small portion of the right tail of the distribution of differences between means, and the null hypothesis would be rejected if and only if the observed differences between the means in hand exceeded the value representing the beginning of the critical region. Critical regions can be defined for tests of hypotheses involving statistics other than means, with similar rationales.

If the alternative to the null hypothesis is the hypothesis of an effect (e.g., a difference between two means) without specification of the direction of the effect (e.g., that Mean_2 is greater than Mean_1), a ‘two-tail’ test of the null hypothesis may be used in which the critical region is composed of two subregions, one on each tail of the distribution. In this case, the area under the curve for each critical subregion would be half the size of the area under the curve in the critical region for a corresponding ‘one-tail’ test.

Cross-classified and Multiple Membership Models

Introduction

Multilevel models also known as variance component models, random effects models and hierarchical linear models, see [5], [7], [14], and [15], have seen rapid growth and development over the last twenty years and are now becoming a standard part of the quantitative social scientist's toolkit (*see Generalized Linear Mixed Models; Linear Multilevel Models*).

Multilevel models provide a flexible regression modeling framework for handling data sampled from clustered population structures (*see Clustered Data*). Examples of clustered population structures are students within classes within schools, patients within hospitals, repeated measurements within individuals or children within families. Ignoring the multilevel structure can lead to incorrect inferences because the standard errors of regression coefficients are incorrect. Also, if the higher-level units are left out of the model we cannot explore questions about the effects of the higher-level units. Most social data have a strong hierarchical structure, which is why multilevel models are becoming so widely used in social science.

The basic multilevel model assumes that the classifications, which determine the multilevel structures, are nested. For example, see Figure 1, which shows a diagram of patients nested within hospitals nested within areas. Often classifications are not nested. Two types of nonnested multilevel models are considered in this chapter, cross-classified models and multiple membership models. These models are also described in [2], [5], [9], [10], and [12]. This entry gives examples of data sets, which have crossed and multiple membership classifications, some diagrammatic tools to help conceptualize these structures and statistical models to describe the structure. We then look at situations where nested, crossed, and multiple membership relationships between classifications can exist in a single population structure and show how the basic diagrams and statistical models are extended to handle this complexity.

Cross-classified Models

Two-way Cross-classifications

Suppose we have data on a large number of high school students and we also know what elementary school they attended and we regard student, high school, and elementary school all as important sources of variation for an educational outcome measure we wish to study. Typically, high schools will draw students from more than one elementary school and elementary schools will send students to more than one high school. The classifications of student, elementary school and high school are not described by a purely nested set of relationships, rather students are contained within a cross-classification of elementary school by high school. Many studies show this simple two-way crossed structure. For example,

- Health: patients contained within a cross-classification of hospital by area of residence
- Survey data: individuals cross-classified by interviewer and area of residence
- Repeated measures cross-classified by the individuals on whom the measurements are made and the set of raters who make the measurements; here different occasions within an individual are assessed by different raters and raters assess many individuals.

Diagrams Representing the Relationship Between Classifications

We find two types of diagrams useful for conveying the relationship between classifications. Firstly, *unit* diagrams where every unit (for example, patient, hospital, and area) appears as a node in the diagram. Lower level units are then connected to higher-level units. A full unit diagram, including all nodes, is prohibitively large. However, a schematic unit diagram conveying the essence of the structure is useful. Figure 2 shows a schematic unit diagram for patients contained within a cross-classification of hospital by area.

The crossing lines in Figure 2 arise because the data structure is cross-classified. When we have many classifications present even the schematic forms of these unit diagrams can be hard to read. In this case an alternative diagrammatic form, which has one node per classification, can be useful. In a *classification* diagram nodes connected by a single arrow represent

2 Cross-classified and Multiple Membership Models

Figure 1 Unit diagram for a nested model

Figure 2 Unit diagram for a cross-classified model

Figure 3 Classification diagrams for crossing and nesting

a nested relationship, nodes connected by a double arrow represent a multiple membership relationship (discussed later), and unconnected nodes represent a cross-classified relationship. Corresponding classification diagrams for the crossed structure in Figure 2 and the completely nested structure in Figure 1 are shown in Figure 3.

Writing the Model Down

In an earlier paper [9], we suggested a notation, which used one subscript per classification, so that

a variance components model for patients within a cross-classification of area by hospital would be written as

$$y_{i(j_1, j_2)} = \beta_0 + u_{j_1} + u_{j_2} + e_{i(j_1, j_2)}, \quad (1)$$

where j_1 indexes hospital, j_2 indexes area and $i(j_1, j_2)$ indexes the i th patient for the cell in the cross-classification defined by hospital j_1 and area j_2 . One problem with this notation is that as more classifications become involved with complex patterns of nesting, crossing, and multiple membership, the subscript formations to describe these patterns become very cumbersome.

An alternative notation, which only involves one subscript no matter how many classifications are present, is given in Browne et al. [2]. In the single subscript notation we write model (1) as:

$$y_i = \beta_0 + u_{\text{area}(i)}^{(2)} + u_{\text{hosp}(i)}^{(3)} + e_i, \quad (2)$$

where i indexes patient and $\text{area}(i)$ and $\text{hosp}(i)$ are functions that return the unit number of the area and hospital that patient i belongs to. For the data structure in Figure 2 the values of $\text{area}(i)$ and $\text{hosp}(i)$ are shown in Table 1. Therefore the model for patient

Table 1 Indexing table for areas by hospitals

i	Area(i)	Hosp(i)
1	1	1
2	2	1
3	2	1
4	1	2
5	3	2
6	1	2
7	2	3
8	3	3
9	1	3
10	2	4
11	3	4
12	2	4

1 would be

$$y_1 = \beta_0 + u_1^{(2)} + u_1^{(3)} + e_1, \quad (3)$$

and for patient 5 would be

$$y_5 = \beta_0 + u_3^{(2)} + u_2^{(3)} + e_5. \quad (4)$$

We use superscripts from 2 upwards to label the random effect corresponding to different classifications reserving the number 1 for the elementary classification. We identify the elementary classification with the letter e . The simplified subscript notation has the advantage that subscripting complexity does not increase as we add more classifications. However, the notation does not describe the patterns of nesting and crossing present. It is therefore useful to use this notation in conjunction with the classification diagrams shown in Figure 3, which display these patterns explicitly.

An Example Analysis for a Two-way Cross-classified Model

Here we look at a two-way cross-classification with students nested within a cross-classification of elementary school by high school. The data comes from Fife in Scotland. The response is the exam score of 3435 children at age 16. There are 19 high schools and 148 elementary schools. We partition variance in the response between student, elementary school, and high school. The classification diagram is shown in Figure 4.

Figure 4 Classification diagram for the Fife educational example

Table 2 Results for the Fife educational data set

Parameter	Description	Estimate(se)
β_0	Mean achievement	5.50 (0.17)
$\sigma_{u^{(2)}}^2$	Elementary school variance	0.35 (0.16)
$\sigma_{u^{(3)}}^2$	High school variance	1.12 (0.20)
σ_e^2	Student variance	8.10 (0.20)

The model is written as:

$$\begin{aligned}
 y_i &= \beta_0 + u_{\text{elem}(i)}^{(2)} + u_{\text{high}(i)}^{(3)} + e_i \\
 u_{\text{elem}(i)}^{(2)} &\sim N(0, \sigma_{u^{(2)}}^2) \\
 u_{\text{high}(i)}^{(3)} &\sim N(0, \sigma_{u^{(3)}}^2) \\
 e_i &\sim N(0, \sigma_e^2).
 \end{aligned} \quad (5)$$

The results in Table 2, show that more of the variation in the achievement at 16 is attributable to high school than elementary school.

Models for More Complex Population Structures

We now consider two examples where the crossed classified structure is more complex than a simple two-way cross-classification.

Social Network Analysis. In social network studies (see **Social Networks**) and family studies we often have observations on how individuals behave or relate to each other. These measurements are often directional. That is we have recorded the amount of behavior from individual A to individual B and also from individual B to individual A. Snijders and Kenny [16] develop a cross-classified multilevel model for handling such data. They use the term *actor* for the individual from whom the behavior originates and the term *partner* for the individual to whom the

4 Cross-classified and Multiple Membership Models

behavior is directed. For a family with two parents and two children, we have 12 directed scores (ds):

$$\begin{aligned} c1 \rightarrow c2, c1 \rightarrow m, c1 \rightarrow f, c2 \rightarrow c1, c2 \rightarrow m, \\ c2 \rightarrow f, m \rightarrow c1, m \rightarrow c2, m \rightarrow f, f \rightarrow c1, \\ f \rightarrow c2, f \rightarrow m \end{aligned}$$

where $c1, c2, f, m$ denote child 1, child 2, father and mother. These directed scores can be classified by actor and by partner. They can also be classified into six dyad groupings:

$$\begin{aligned} (c1 \rightarrow c2, c2 \rightarrow c1), (c1 \rightarrow m, m \rightarrow c1), \\ (c1 \rightarrow f, f \rightarrow c1), (c2 \rightarrow m, m \rightarrow c2), \\ (c2 \rightarrow f, f \rightarrow c2), (m \rightarrow f, f \rightarrow m) \end{aligned}$$

Schematically, the structure is as shown in Figure 5.

Note that the notion of a classification is different from the set of units contained in a classification. For example, the actor and partner classifications are made up of the same set of units (family members). What distinguishes the actors and partners as different classifications is that they have a different set of

connections (or a different mapping) to the level 1 units (directed scores). See [2] for a mathematical definition of classifications as mappings between sets of units.

In this family network data the directed scores are contained within a cross-classification of actors, partners, and dyads and this crossed structure is nested within families. The classification diagram for this structure is shown in Figure 6.

The model can be written as:

$$\begin{aligned} y_i &= (X\beta)_i + u_{\text{actor}(i)}^{(2)} + u_{\text{partner}(i)}^{(3)} + u_{\text{dyad}(i)}^{(4)} \\ &\quad + u_{\text{family}(i)}^{(5)} + e_i \\ u_{\text{actor}(i)}^{(2)} &\sim N(0, \sigma_{u(2)}^2), \quad u_{\text{partner}(i)}^{(3)} \sim N(0, \sigma_{u(3)}^2) \\ u_{\text{dyad}(i)}^{(4)} &\sim N(0, \sigma_{u(4)}^2) \\ u_{\text{family}(i)}^{(5)} &\sim N(0, \sigma_{u(5)}^2), \quad e_i \sim N(0, \sigma_e^2). \end{aligned} \quad (6)$$

These models have not been widely used but they offer great potential for decomposing between and within family dynamics. They can address questions such as:

Figure 5 Unit diagram for the family network data

Figure 6 Classification diagram for family network data

how stable are an individual's actor effects across other family members?
 how stable are an individual's partner effects across other family members?
 what are the relative sizes of family, actor, partner, and dyad effects?

The reader is directed to [16] for a more detailed exposition on these models and some example analyses.

A Medical Example. We consider a data set concerning artificial insemination by donor shown in

Figure 7. A detailed description of this data set and the substantive research questions addressed by modeling it within a cross-classified framework are given in Ecochard and Clayton [4]. The data were reanalyzed by Clayton and Rasbash [3] as an example demonstrating the properties of a data augmentation algorithm for estimating cross-classified models.

The data consist of 1901 women who were inseminated by sperm donations from 279 donors. Each donor made multiple donations and there were 1328 donations in all. A single donation is used for multiple inseminations. Each woman received a series of inseminations, one per ovulatory cycle. The data contain 12 100 ovulatory cycles within the 1901 women. The response is a binary variable indicating whether conception occurs in a given cycle.

There are two crossed hierarchies, a hierarchy for donors and a hierarchy for women. The women hierarchy is cycles within women and the donor hierarchy is cycles within donations within donors. Within a series of cycles a women may receive sperm from multiple donors/donations. The model is schematically represented Figure 7.

Here cycles are positioned on the diagram within women, so the topology of the diagram reflects the hierarchy for women. When we connect the male hierarchy to the diagram we see crossing connections between donations and cycles, revealing the crossed structure of the data set. The classification diagram for this structure is shown in Figure 8.

Figure 7 Unit diagram for the artificial insemination example

Figure 8 Classification diagram for the artificial insemination example

We can write the model as

$$\begin{aligned}
 y_i &\sim \text{Binomial}(1, \pi_i) \\
 \text{logit}(\pi_i) &= (X\beta)_i + u_{\text{woman}(i)}^{(2)} + u_{\text{donation}(i)}^{(3)} + u_{\text{donor}(i)}^{(4)} \\
 u_{\text{woman}(i)}^{(2)} &\sim N(0, \sigma_{u(2)}^2) \\
 u_{\text{donation}(i)}^{(3)} &\sim N(0, \sigma_{u(3)}^2) \\
 u_{\text{donor}(i)}^{(4)} &\sim N(0, \sigma_{u(4)}^2). \tag{7}
 \end{aligned}$$

The results are shown in Table 3. Azoospermia is a dichotomous variable indicating whether the fecundability of the women is not impaired. The probability of conception is increased with azoospermia and increased sperm motility, count, and quality but decreases in older women or if insemination is attempted too early or late in the monthly cycle. After

Table 3 Results for the artificial insemination data

Parameter	Description	Estimate(se)
β_0	Intercept	-3.92 (0.21)
β_1	Azoospermia	0.21 (0.09)
β_2	Semen quality	0.18 (0.03)
β_3	Women's age >35	-0.29 (0.12)
β_4	Sperm count	0.002 (0.001)
β_5	Sperm motility	0.0002 (0.0001)
β_6	Insemination too early	-0.69 (0.17)
β_7	Insemination too late	-0.27 (0.09)
$\sigma_{u(2)}^2$	Women variance	1.02 (0.15)
$\sigma_{u(3)}^2$	Donation variance	0.36 (0.074)
$\sigma_{u(4)}^2$	Donor variance	0.11 (0.06)

inclusion of covariates, there is considerably more variation in the probability of a successful insemination attributable to the women hierarchy than the donor/donation hierarchy.

Multiple Membership Models

In the models we have fitted so far, we have assumed that lower level units are members of a single unit from each higher-level classification. For example, students are members of a single high school and a single elementary school. Where lower-level units are influenced by more than one higher-level unit from the same classification, we have a multiple membership model. For example, if patients are treated by several nurses, then patients are “multiple members” of nurses. Each of the nurses treating a patient contributes to the patient’s treatment outcome. In this case the treatment outcome for patient i is modeled by a fixed predictor, a weighted sum of the random effects for the nurses that treat patient i and a patient level residual. This model can be written as

$$\begin{aligned}
 y_i &= (X\beta)_i + \sum_{j \in \text{nurse}(i)} w_{i,j}^{(2)} u_j^{(2)} + e_i \\
 u_j^{(2)} &\sim N(0, \sigma_u^2) \\
 e_i &\sim N(0, \sigma_e^2) \\
 \sum_{j \in \text{nurse}(i)} w_{i,j}^{(2)} &= 1 \tag{8}
 \end{aligned}$$

where $\text{nurse}(i)$ is the set of nurses treating patient i and $w_{i,j}^{(2)}$ is the weight given to nurse j for patient i . To clarify this, let’s look at the situation for the first four patients. The weighted membership matrix is shown in Table 4, where patient 1 is treated 0.5 of the time by nurse 1 and 0.5 of the time by nurse 3, patient 2 is seen only by nurse 1 and so on.

Writing out the model for the first four patients gives:

$$\begin{aligned}
 y_1 &= X_1\beta + 0.5u_1^{(2)} + 0.5u_3^{(2)} + e_1 \\
 y_2 &= X_2\beta + 1.0u_1^{(2)} + e_2 \\
 y_3 &= X_3\beta + 0.5u_2^{(2)} + 0.5u_3^{(2)} + e_3 \\
 y_4 &= X_4\beta + 0.5u_1^{(2)} + 0.5u_2^{(2)} + e_4. \tag{9}
 \end{aligned}$$

Table 4 An example weighted membership matrix for patients and nurses

	Nurse 1 ($j = 1$)	Nurse 2 ($j = 2$)	Nurse 3 ($j = 3$)
Patient 1 ($i = 1$)	0.5	0	0.5
Patient 2 ($i = 2$)	1	0	0
Patient 3 ($i = 3$)	0	0.5	0.5
Patient 4 ($i = 4$)	0.5	0.5	0

**Figure 9** Unit diagram for patient nurse classification structure**Figure 10** Classification diagram for patient nurse classification structure

The unit diagram for this structure is shown in Figure 9 and the classification diagram, which denotes multiple membership with a double arrow, is shown in Figure 10.

Combining Nested, Crossed, and Multiple Membership Structures

If we extend the patient/nurse example so that nurses are nested within hospitals and patients' area of residence is crossed with hospitals, we now have a model containing two crossed hierarchies. The first hierarchy is patient within area and the second hierarchy is patients within nurses within hospital, where patients are multiple members of nurses. The

**Figure 11** Classification diagram for nested, crossed multiple membership structure

classification diagram for this structure is shown in Figure 11.

An Example Analysis Combining Nested, Crossed, and Multiple Membership Classifications

The example considered is from veterinary epidemiology. The data has been kindly supplied by Mariann Chriel. It is concerned with causes and sources of variability in outbreaks of salmonella in flocks of chickens in poultry farms in Denmark between 1995 and 1997. The data have a complex structure. There are two main hierarchies in the data. The first is concerned with production. Level 1 units are flocks of chickens and the response is binary, whether there was any instance of salmonella in the flock. Flocks live for a short time, about two months, before they are slaughtered for consumption. Flocks are kept in houses, so in a year a house may have a throughput of five or six flocks. Houses are grouped together in farms. There are 10 127 child flocks in 725 houses in 304 farms.

The second hierarchy is concerned with breeding. There are two hundred parent flocks in Denmark; eggs are taken from parent flocks to four hatcheries. After hatching, the chicks are transported to the farms in the production hierarchy, where they form the production (child) flocks. Any given child flock may draw chicks from up to six parent flocks. Child flocks are therefore multiple members of parent flocks. Chicks from a single parent flock go to many production farms and chicks on a single production

8 Cross-classified and Multiple Membership Models

Figure 12 Unit diagram for Danish poultry example

farm come from more than one parent flock. This means the multiple membership breeding hierarchy is cross-classified with the production hierarchy. A unit diagram for the structure is shown in Figure 12 and a classification diagram in Figure 13.

We can write the model as

$$\begin{aligned}
 y_i &\sim \text{Bin}(\pi_i, 1) \\
 \text{logit}(\pi_i) &= (XB)_i + u_{\text{house}(i)}^{(2)} + u_{\text{farm}(i)}^{(3)} \\
 &\quad + \sum_{j \in \text{parent}(i)} w_{i,j}^{(4)} u_j^{(4)} \\
 u_{\text{house}(i)}^{(2)} &\sim N(0, \sigma_{u(2)}^2), \quad u_{\text{farm}(i)}^{(3)} \sim N(0, \sigma_{u(3)}^2)
 \end{aligned}$$

Figure 13 Classification diagram for Danish poultry example

Table 5 Results for Danish poultry data

Parameter	Description	Estimate(se)
β_0	Intercept	-1.86 (0.187)
β_1	1996	-1.04 (0.131)
β_2	1997	-0.89 (0.151)
β_3	Hatchery 2	-1.47 (0.22)
β_4	Hatchery 3	-0.17 (0.21)
β_5	Hatchery 4	-0.92 (0.29)
$\sigma_{u(2)}^2$	House variance	0.19 (0.09)
$\sigma_{u(3)}^2$	Farm variance	0.59 (0.11)
$\sigma_{u(4)}^2$	Parent flock variance	1.02 (0.22)

$$u_j^{(4)} \sim N(0, \sigma_{u(4)}^2). \quad (10)$$

Five covariates were considered in the model: year = 1996, year = 1997, hatchery = 2, hatchery = 3, hatchery = 4. The intercept corresponds to hatchery 1 in 1995. The epidemiological questions of interest revolve around how much of the variation of salmonella incidence is attributable to houses, farms, and parent flocks. The results in Table 5 show there is a large parent flock variance indicating that a parent flock process is having a substantial effect on the variability in the probability of child flock infection. This could be due to genetic variation across parent flocks in resistance to salmonella, or it may be due to differential hygiene standards in parent flocks. There is also a large between farm variance and a relatively small between house within farm variance.

Estimation Algorithms

All the models in this paper were fitted using MCMC estimation [1] (*see Markov Chain Monte Carlo and Bayesian Statistics*) in the *MLwiN* software package [11]. MCMC algorithms for cross-classified and multiple membership models are given by Browne et al. [2]. Two alternative algorithms available in *MLwiN* for cross-classified models are an Iterative Generalised Least Squares (IGLS) algorithm [12] and a data augmentation algorithm [3]. In a forthcoming book chapter Rasbash and Browne [10] give an overview of these algorithms for cross-classified models and compare results for the different estimation procedures. They also give details of an IGLS algorithm for multiple membership models.

Raudenbush [13] gives an empirical Bayes algorithm for two-way cross-classifications. Pan and Thompson [8] give a Gauss–Hermite quadrature algorithm for cross-classified structures and Lee and Nelder [6] give details of an Hierarchical Generalised Linear Model (HGLM), which can handle cross-classified structures.

Summary

Many data sets in the social, behavioral, and medical sciences exhibit crossed and multiple membership structures. This entry sets out some statistical models and diagrammatic tools to help conceptualize and model data with this structure.

Cross-lagged Panel Design

A cross-lagged panel design is simple to describe. Two variables, X and Y , are measured at two times, 1 and 2, resulting in four measures, X_1 , Y_1 , X_2 , and Y_2 . With these four measures, there are six possible relations among them – two synchronous or cross-sectional relations (*see* **Cross-sectional Design**) (between X_1 and Y_1 and between X_2 and Y_2), two stability relations (between X_1 and X_2 and between Y_1 and Y_2), and two cross-lagged relations (between X_1 and Y_2 and between Y_1 and X_2). As is typical in most considerations of the design, X and Y are treated as continuous variables.

As an example of cross-lagged panel design, Bentler and Speckart [1] examined the variables attitudes to alcohol and alcohol behavior (i.e., consumption) measured at two times. Their key research question was whether attitudes determined behavior or whether behavior determined attitudes.

Despite the simplicity in defining the design, there is considerable debate and difficulty in the statistical analysis of the data from such a design. By far, the most common analysis strategy is to employ **multiple linear regression**. Each measure at the second time or wave is predicted by the set of time-one measures. The measure X_2 is predicted by both X_1 and Y_1 , and Y_2 is predicted by X_1 and Y_1 . The result is four regression coefficients, two of which are stabilities and two of which are cross-lagged. Many assumptions are required before these cross-lagged relations can be validly interpreted as causal effects. Among them are (1) no measurement error in the time-one measures, (2) no unmeasured third variables that cause both X and Y , and (3) the correct specification of the causal lag. One strategy for handling the problem of measurement error is to employ a **latent variable** analysis (*see* **Structural Equation Modeling: Overview**) ([1]). However, it is much more difficult to know whether the assumptions of no unmeasured variables and correct specification of the causal lag have been met.

An alternative and rarely used approach was developed from Campbell's [2] cross-lagged panel correlation, or CLPC. For this approach, we begin with the assumption that the association between X and Y is due to some unmeasured latent variable.

That is, it is assumed that there are no direct causal effects between the two variables. As discussed by Kenny [3], given assumptions about certain parameters, such a model implies that the two cross-lagged relations should be equal. Also infrequently used are methods based on computing the relations using the average of each variable, $(X_1 + X_2)/2$, and their difference $X_2 - X_1$ ([4]).

Almost always there are additional variables in the model. More than two variables are being measured at both times. Other variables are demographic or control variables. Sometimes there are also intermediary variables (variables that measure what happens between time points). One additional complication arises in that typically some of the units that are measured at time one are not measured at time two, and less frequently some of those measured at time two are not measured at time one. Finally, it may not be clear that X and Y are 'measured at the same time'.

Several analysts (e.g., Singer & Willett [5]) have argued that two time points are insufficient to make strong causal claims about the relations between the variables. Thus, while a cross-lagged panel design might provide some information about causal ordering, it may be less than optimal.

Crossover Design

In experimental settings where the effects of treatments are reversible, and comparatively short-lived, the potential exists for increasing the precision of treatment effects through the use of within-subject comparisons: if repeated measurements (*see Repeated Measures Analysis of Variance*) on a subject are highly correlated, then differences among these will be much more precise than the differences among the same outcomes measured on different subjects. A *crossover design* exploits this by using repeated measurements from each subject under different treatments, and the gain in terms of precision compared with a **completely randomized design** increases with increasing within-subject **correlation**.

With two treatments (A and B, say) we might consider giving all the subjects A followed after a suitable gap by B. Such a design is flawed, however, because we cannot separate the effect of time or order of treatment from the treatment comparison itself. We can circumvent this problem by randomly allocating half the subjects to receive the treatments in the order AB and half in the order BA. When the treatment difference is calculated from such a design, any effects associated with time (termed *period effects*) cancel out. This simple design is known as the two-period two-treatment, or 2×2 , crossover. In an example described in [2, Section 2.11], this design was used in the investigation of the relationship between plasma estradiol levels in women and visuospatial ability. The ‘treatments’ in this case were defined by periods of relatively low- and high-estradiol levels in women undergoing *in-vitro* fertilization, with the women randomized to start the trial at either the high level or the low level.

Crossover designs have potential disadvantages along with the benefits. After the first period, subjects in different sequences have experienced different treatment regimes and are therefore not comparable in the sense of a completely randomized design. The justification for inferences about treatment effects cannot be based purely on **randomization** arguments. Additional assumptions are required, principally, that previous treatment allocation does not affect subsequent treatment comparisons. If this is *not* true, there is said to be a **carryover effect**. There are

many ways in which carryover effects can in principle occur. For example, in an experiment with drugs as treatments, it may be that these have not cleared a subject’s system completely at the end of a period, and so continue to affect the response in the following period. Often *washout* periods, intervals without treatment, are used between treatment periods to minimize the likelihood of this. Sometimes, for practical reasons, washout periods may not be possible, and other forms of carryover may be unaffected by washout periods. Another source of potential problem is the existence of treatment-by-period interaction. Should there be nonnegligible changes over time in response, learning effects being one common cause of this, it is possible in some settings that treatment comparisons will differ according to the period in which they are made. In the two-period two-treatment design, there is little that can be done about such problems, and the conclusions from such experiments rest on the assumption that carryover effects and treatment-by-period interaction are small compared to the direct treatment comparison.

There are many other crossover designs that may be used and each has particular practical and theoretical advantages and disadvantages. In particular, many allow the separation of direct treatment, carryover, and treatment-by-period effects. Although this may seem advantageous, such separation is always still firmly based on modeling assumptions that cannot be fully checked from the data under analysis. Also, correction for many extra terms can lead to great inefficiency. Hence, such statistical manipulations and corrections should not be seen as a blanket solution to the issues surrounding the assumptions that need to be made when analyzing crossover data.

In general, a crossover design may have more than two treatments, more than two periods, and more than two sequences. For a full description of the many crossover designs that have been proposed, see [2, Chapters 3 and 4]. One common feature of all crossover designs is the requirement that there be at least as many sequences as treatments, for otherwise it is not possible to separate treatment and period effects.

Practical restrictions permitting, it is generally desirable to balance as far as possible, the three main components of the design, that is, sequences, periods, and treatments, and this implies that the

number of periods will equal the number of treatments. Examples of such designs that are in perfect balance are so-called balanced **Latin square designs** in which each treatment occurs equally often in each period and each sequence [2, Section 4.2]. These are the most efficient designs possible, provided no adjustment need be made for other effects such as carryover. Additional forms of balance can be imposed to maintain reasonable efficiency when adjusting for simple forms of carryover effect, the so-called *Williams squares* are the commonest example of these.

The analysis of continuous data from crossover trials usually follows conventional factorial ANOVA type procedures (*see Factorial Designs*), incorporating fixed subject effects (*see Fixed and Random Effects*) [1; 2, Chapter 5]. This maintains simplicity but does confine the analysis to within-subject information only. In efficient designs, most or all information on treatment effects is within-subject, so it is rarely sensible to deviate from this approach. However, it is sometimes necessary to use designs that are not efficient, for example, when the number of treatments exceeds the number of periods that can be used, and for these it is worth considering the recovery of *between-subject* or inter-block information. This is accomplished by using an analysis with

random as opposed to fixed subject effects (*see Fixed and Random Effects*). In psychological research, it is not unusual to have crossover designs with very many periods in which treatments are repeated. In the analysis of data from such trials, there are potentially many period parameters. For the purposes of efficiency, it may be worth considering replacing the categorical period component by a smooth curve to represent changes over time; a polynomial or non-parametric smooth function might be used for this [2, Section 5.8]. For analyzing nonnormal, particularly, categorical data, appropriate methods for nonnormal clustered or repeated measurements data (*see Generalized Linear Mixed Models*) can be adapted to the crossover setting [2, Chapter 6].

Cross-sectional Design

Cross-sectional research involves collecting data at the same time from groups of individuals who are of different ages or at different stages of development. Suppose a researcher is interested in studying self-concept of girls as they mature. It would take a long time to collect data on a group of first-grade girls following them through graduation from high school, measuring their self-concept every few years. Instead, the researcher could select samples of girls in the first, fourth, seventh, tenth, and twelfth grades and measure the self-concept of the girls in each of the samples. Differences between average self-concept scores at the different grade levels could be interpreted as reflecting developmental changes in female self-concept.

Longitudinal research (*see* **Longitudinal Data Analysis**) is a study of changes of a sample over time. There are several disadvantages to conducting a longitudinal research study. The study takes a long time to complete, and subjects are lost over the time period. As an alternative, researchers have turned to cross-sectional studies where large groups are studied at one time. Instead of studying one group over time, cohorts are investigated at the same time. The cohorts usually vary on the basis of age, stages of development, or different points in a temporal sequence, for example, college graduates, those with an M.A. degree, and those with a Ph.D. or Ed.D. degrees (*see* **Cohort Studies**). The advantage is that a study can be conducted in a relatively short period of time and with little loss of subjects. The major disadvantage is that any differences between the cohorts based on the variable or variables under study are confounded with cohort differences, which may be due to age differences or other extraneous factors unrelated to those being investigated. The confounding that can occur in the cross-sectional design may be attributed to personological or environmental variables or to the subjects' history and is called a *cohort effect*. The larger the difference in the variable for the cohort groups, then the greater potential for cohort effects, that is, if age is the variable that is the basis for the cohort, then the greater the age differences, the more likely subject history may contribute to cohort differences than the variable under investigation. In fact, if the age groups include an extremely large

range, then generational differences may be the confounding factor. If individuals are matched across cohorts on relevant variables, then the effects of subject history may be diminished. Another problem with cross-sectional designs is selecting samples that truly represent the individuals at the levels being investigated.

Many developmental studies employ a cross-sectional design. If a researcher is interested in developmental trends or changes in moral beliefs, a sample of students may be taken from different grade levels, for example, fourth, sixth, eighth, tenth, and twelfth. The students would be administered the moral beliefs instrument at about the same time in all of the grades and analyze for trends. Given that the data are collected within the same time period, individuals will not be lost over time owing to moving out of the area, death, and so on. **Factorial designs** can be employed within each of the cohorts. Using the same moral beliefs example, if the researcher were interested in gender and ethnic differences, then those variables would be assessed and analyzed. Main effects for age, gender, and development may be tested along with the interactions between these variables.

Nesselroade and Baltes [2, p. 265] have argued that 'cross-sectional designs confound interindividual growth and consequently are not adequate for the study of developmental processes'. Their premise is that repeated measurements on the same individual are essential for the assessment of individual growth and change (*see* **Growth Curve Modeling**). Purkey [3], however, used a number of cross-sectional studies to establish a persistent relationship between measures of self-concept and academic achievement. Causal inferences cannot be made from Purkey's cross-sectional studies, however, only from longitudinal research, which points to the limitations of cross-sectional studies.

As an example of a repeated cross-sectional design, consider the High School and Beyond (HS&B) Study [1] that began in 1980 and sampled 1647 high-school students from all regions of the United States. The HS&B survey included two cohorts: the 1980 senior class and the 1980 sophomore class. Both cohorts were surveyed every 2 years through 1986, and the 1980 sophomore class was also surveyed again in 1992. The purpose of the study was to follow students as they began to take on adult roles. A cross-sectional study

2 Cross-sectional Design

would include seniors, individuals with 2-, 4-, and 6-years graduation in the same geographic regions, same gender composition, and same socioeconomic status.

Additional information on repeated cross-sectional studies can be found under **cohort sequential designs** under accelerated longitudinal designs.

Cross-validation

In a generic regression problem (see **Regression Models**), we want to model the dependence of a *response variable* Y on a collection $\mathbf{X} = (X_1, \dots, X_m)$ of *predictor variables*, based on a *training sample* $\mathcal{T} = (\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)$. The kinds of models as well as the goodness-of-fit criteria depend on the nature of the response variable Y . If Y is a continuous variable, we might fit a linear model by least squares, whereas for binary Y , we might use **logistic regression** or **discriminant analysis**. In the following, we will focus on the case of continuous response, but the ideas are very general.

Goals of Regression Analysis

There are (at least) two goals of regression analysis. The first one is to ‘understand how Y depends on $\mathbf{X}$.’ By this, we mean making statements like ‘ Y tends to increase as X_1 increases’ or ‘ X_5 seems to have little influence on Y .’ If we used a **linear model**

$$Y \sim b_0 + b_1 X_1 + \dots + b_m X_m, \quad (1)$$

we would base such statements on the estimated regression coefficients $\hat{b}_1, \dots, \hat{b}_m$. If the predictor variables are correlated – the usual situation for observational data – such interpretations are not at all innocuous; Chapters 12–13 of Mosteller and Tukey [2] contain an excellent discussion of the problems and pitfalls.

The second goal, and the one we will focus on, is prediction: generate a *prediction rule* $\phi(\mathbf{x}; \mathcal{T})$ that predicts the value of the response Y from the values $\mathbf{x} = (x_1, \dots, x_m)$ of the predictor variables. In the case of a linear model, an obvious choice is

$$\phi(\mathbf{x}; \mathcal{T}) = \hat{b}_0 + \hat{b}_1 x_1 + \dots + \hat{b}_m x_m, \quad (2)$$

where the regression coefficients are estimated from the training sample $\mathcal{T}$.

In the social and behavioral sciences, the dominant goal has traditionally been to understand how the response depends on the predictors. Even if understanding is the primary goal, it might still be prudent, however, to evaluate the predictive performance of a model. Low predictive power can indicate a lack of

understanding of the underlying mechanisms and may call any conclusions into question.

Measuring the Performance of a Prediction Rule

Once we have generated a prediction rule from our training sample, we want to assess its performance. We first have to choose a *loss function* $L(y, \hat{y})$ that specifies the damage done if the rule predicts $\hat{y}$, but the true response is y . A standard choice for continuous response is squared error loss: $L(y, \hat{y}) = (y - \hat{y})^2$. We then measure performance by the *risk* of the rule, the expected loss when applying the prediction rule to new *test observations* assumed to be randomly drawn from the same population as the training observations. For squared error loss, the case we will consider from now on, the risk is

$$R(\phi) = E((Y - \phi(\mathbf{X}; \mathcal{T}))^2), \quad (3)$$

where the expectation is taken over the population distribution of $(\mathbf{X}, Y)$. The question is how to estimate this risk.

Example

We now describe a simple example which we will use to illustrate risk estimation. There are $m = 50$ predictor variables that are independent and uniformly distributed on the unit interval $[0, 1]$. The response Y is a linear function of the predictors, plus Gaussian noise ϵ with mean 0 and variance σ^2 :

$$Y = b_1 X_1 + \dots + b_m X_m + \epsilon. \quad (4)$$

Each of the true regression coefficients $b_1, \dots, b_m$ is zero with probability 0.8, and an observation of a standard Gaussian with probability 0.2. Therefore, only about 10 of the true regression coefficients will be nonvanishing. The noise variance σ^2 is chosen to be the same as the ‘signal variance’:

$$\sigma^2 = \mathbf{V}(b_1 X_1 + \dots + b_m X_m). \quad (5)$$

The Resubstitution Estimate of Risk

The simplest and most obvious approach to risk estimation is to see how well the prediction rule does

2 Cross-validation

for the observations in the training sample. This leads to the *resubstitution estimate* of risk

$$\hat{R}_{\text{resub}}(\phi) = \frac{1}{n} \sum (y_i - \phi(\mathbf{x}_i; \mathcal{T}))^2, \quad (6)$$

which is simply the average squared residual for the training observations. The problem with the resubstitution estimate is that it tends to underestimate the risk, often by a substantial margin. Intuitively, the reason for this optimism is that, after all, the model was chosen to fit the training data well.

To illustrate this effect, we generated a training sample $\mathcal{T}$ of size $n = 100$ from the model described in the previous section, estimated regression coefficients by least squares, and constructed the prediction rule (2). The resubstitution estimate of risk is $\hat{R}_{\text{resub}}(\phi) = 0.64$. Because we know the population distribution of $(\mathbf{X}, Y)$, we can compute the true risk of the rule: We generate a very large ($N = 10\,000$) *test set* of new observations from the model and evaluate the average loss incurred when predicting those 10 000 responses from the corresponding predictor vectors. The true risk turns out to be $R(\phi) = 3.22$; the resubstitution estimate underestimates the risk by a factor of 5!

Of course, this result might be a statistical fluke – maybe we just got a bad training sample? To answer this question, we randomly generated 50 training samples of size $n = 100$, computed the true risk and the resubstitution estimate for each of them, and averaged over training samples. The average resubstitution estimate was 0.84, while the average true risk was 3.48; the result was not a fluke.

The Test Set Estimate of Risk

If we had a large data set at our disposal – a situation not uncommon in this age of automatic, computerized data collection – we could choose not to use all the data for making up our prediction rule. Instead, we could use half the data as the training set $\mathcal{T}$ and compute the average loss when making predictions for the test set. The average loss for the test set is an unbiased estimate for the risk; it is not systematically high or systematically low.

Often, however, we do not have an abundance of data, and using some of them just for estimating the risk of the prediction rule seems wasteful, given that we could have obtained a better rule by using all the data for training. This is where cross-validation comes in.

The Cross-validation Estimate of Risk

The basic idea of cross-validation, first suggested by Stone [3] is to use each observation in both roles, as a training observation and as a test observation. Cross-validation is best described in algorithmic form:

Randomly divide the training sample $\mathcal{T}$ into k subsets $\mathcal{T}_1, \dots, \mathcal{T}_k$ of roughly equal size (choice of k is discussed below). Let $\mathcal{T}^{-i}$ be the training set with the i -th subset removed.

For $i = 1 \dots k$ {

- Generate a prediction rule $\phi(\mathbf{x}, \mathcal{T}^{-i})$ from the training observations not in the i -th subset.
- Compute the total loss L^i when using this rule on the i -th subset:

$$L^i = \sum_{j \in \mathcal{T}^i} (y_j - \phi(\mathbf{x}_j, \mathcal{T}^{-i}))^2 \quad (7)$$

}

Compute the cross-validation estimate of risk

$$\hat{R}_{\text{cv}}(\phi) = \frac{1}{n} \sum_{i=1}^k L^i. \quad (8)$$

In our example, the cross-validation estimate of risk is $\hat{R}_{\text{cv}} = 2.87$, compared to the true risk $R = 3.22$, and the resubstitution estimate $\hat{R}_{\text{resub}} = 0.64$. So the cross-validation estimate is much closer to the true risk than the resubstitution estimate. It still underestimates the risk, but this is a statistical fluke. If we average over 50 training samples, the average cross-validation estimate is 3.98. The cross-validation estimate of risk is not optimistic, because the observations that are predicted are not used in generating the prediction rule. In fact, cross-validation tends to be somewhat pessimistic, partly because it estimates the performance of a prediction rule generated from a training sample of size roughly $n(1 - 1/k)$.

A question which we have not yet addressed is the choice of k . In some situations, such as linear least squares, leave-one-out cross validation, corresponding to $k = n$, has been popular, because it can be done in a computationally efficient way. In general, though, the work load increases with k because we have to generate k prediction rules instead of one. Theoretical analysis of cross-validation has proven to be surprisingly difficult, but a general consensus, based mostly

on empirical evidence, suggests that $k = 5$ or 10 is reasonable (see [1, Chapter 7.10]).

Using Cross-validation for Model Selection

In a situation like the one in our example, where we have many predictor variables and a small training sample, we can often decrease the prediction error by reducing model complexity. A well-known approach to reducing model complexity in the context of linear least squares (see **Least Squares Estimation**) is *stepwise regression*: Find the predictor variable that, by itself, best explains Y ; find the predictor variable that best explains Y when used together with the variable found in step 1; find the variable that best explains Y when used together with the variables found in steps 1 and 2; and so on. The critical question is when to stop adding more variables.

The dotted curve in Figure 1 shows the resubstitution estimate of risk – the average squared residual – plotted against the number of predictor variables in the model. It is not helpful in choosing a good model size.

The dashed curve shows the cross-validation estimate of risk. It is minimized for a rule using six predictor variables, suggesting that we should end the process of adding variables after six steps.

The solid curve shows the true risk. It exhibits the same pattern as the cross-validation estimate and is

Figure 1 True risk (solid), resubstitution estimate (dotted) and cross-validation estimate (dashed) for a single training sample as a function of the number of predictor variables

Figure 2 Average of true risk (solid), resubstitution estimate (dotted) and cross-validation estimate (dashed) over 50 training samples as a function of the number of predictor variables

also minimized for a model with six variables. This is not surprising, given that only about 10 of the true regression coefficients are nonvanishing, and some of the remaining ones are small. Adding more predictor variables basically just models noise in the training sample; complex models typically do not generalize well.

Figure 2 shows the corresponding plot, but the curves are obtained by averaging over 50 training samples. Note that the cross-validation estimate of risk tracks the true risk well, especially for the lower ranges of model complexity, which are the practically important ones.

Alternatives to Cross-validation

Many alternatives to cross-validation have been suggested. There is **Akaike's Information Criterion (AIC)**, the **Bayesian Information Criterion (BIC)**, **Minimum Description Length (MDL)**, and so on; see [1, Chapter 7] for a survey and references. These criteria all consist of two components: a measure of predictive performance for the training data, and a penalty for 'model complexity.' In principle, this makes sense – more complex models are more prone to modeling the noise in the training data, which makes the resubstitution estimate of risk more optimistic. However, it is often not obvious how to

measure model complexity, and the degree of optimism depends not only on the set of models under consideration but also on the thoroughness of the search process, the amount of data dredging. There are also risk estimates based on the **bootstrap**, which are similar in spirit to cross-validation, in that they substitute calculations on a computer for mathematical derivation of mostly asymptotic results. Overall, though, cross-validation is appealing because it is intuitive, easy to understand, and trivial to implement.

Cultural Transmission

Cultural transmission facilitates the transfer, via teaching and imitation, of the knowledge, values, and other factors of a civilization that influence behavior. Cultural transmission creates novel evolutionary processes through the existence of socially transmitted traditions that are not directly attributable to genetic factors and immediate environmental contingencies; instead, social learning *interacts* with environmental contingencies to produce behavior (*see* **Gene-Environment Interaction**). As a nongenetic form of evolution by natural selection, if the behavior that arises from cultural forces is not adaptive, it will not be transmitted across generations. Thus, the relationship between culture and behavior created by cultural transmission is analogous to the relationship between **genotype** and phenotype caused by genetic transmission.

Cultural transmission is not simply another term to describe how the 'environment' influences behavior. Behavior caused by cultural transmission must itself be modifiable in later generations by cultural influences contemporary to that generation. For example, the local climate and the kinds of food items available are part of the population's environment but are not affected by evolutionary changes in the population. Individuals form the environment relevant to cultural transmission.

Cultural transmission also relies specifically on social learning and not on other forms of learning. Learning mechanisms that influence a specific individual's behavior, and not the population, are not relevant to cultural transmission. For instance, given a criterion of reinforcement, such as a sense of pain or a taste for rewards, behavior will change. Behaviors acquired through reinforcement schedules are lost with the individual's death; culturally acquired behaviors are transmitted from generation to generation, and like genes, they are evolving properties of the population.

Different types of cultural transmission can be defined. Vertical transmission refers to transmission from parents to offspring, and can be uniparental or biparental. Vertical transmission does not require genetic relatedness – adoptive parents can transfer knowledge to their adopted children. Horizontal transmission refers to transmission between any two individuals, related or not, who are of the

same generation, such as siblings and age peers. Oblique transmission occurs from a member of a given generation to a later generation, but does not include parent–offspring transmission (which is specific to vertical transmission). Examples of oblique sources of cultural information are members of society in general, family members other than parents, and teachers.

Mathematical models of cultural transmission can be placed in two categories: (a) evolutionary models (e.g., [1, 2]), and (b) behavior genetic models (e.g., [5]). Evolutionary models emphasize similarities among individuals within a population, while behavior genetic models emphasize differences among individuals within a population.

Cultural transmission can create correlations between genotypes and environments. **Genotype–environment correlation** refers to a correlation between the genetic and environmental influences affecting a trait. As in any other correlation, where certain values of one variable tend to occur in concert with certain values of another variable, a significant genotype–environment correlation represents the nonrandom distribution of the values of one variable (genotype) across the values of another variable (environment).

Passive genotype–environment correlation [8] arises from vertical cultural transmission. That is, because parents and their offspring are on the average 50% genetically related, both genes and cultural influences are transmitted to offspring from a common source (parents), inducing a correlation between genotypes and the environment. Genotype–environment correlation can also arise through horizontal cultural transmission. In sibling effects (*see* **Sibling Interaction Effects**) models [3, 4], sibling pairs are specified as sources of horizontal transmission. When siblings compete or cooperate, genotype–environment correlation occurs if the genes underlying a trait in one sibling also influence the environment of the cosibling. Reactive genotype–environment correlation [7] can result from oblique cultural transmission. In this type of correlation, society reacts to the *level* of an individual's genetically influenced behavior by providing cultural information that it might not provide to other individuals who do not show the same level of behavior. For example, children who show unusual talent for the violin will more likely be instructed by masters of the violin

2 Cultural Transmission

than those children who do not demonstrate such talent. Active genotype–environment correlation [6] can also arise from oblique cultural transmission: Individuals select certain cultural artifacts on the basis of genetically influenced proclivities. The child with unusual talent for the violin will choose to master that musical instrument over the piano.

Data Mining

Data mining is the technology of discovering structures and patterns in large data sets. From this definition, it will be immediately apparent that the discipline has substantial overlap with other data analytic disciplines, especially statistics, machine learning, and **pattern recognition**. However, while there is substantial overlap, each of these disciplines has its own emphasis. Data mining, in particular, is distinguished from these other disciplines by the (large) size of the data sets, often by the poor quality of the data, and by the breadth of the kind of structures sought. Each of these aspects is explored in more detail below.

Data mining exercises and tools can be conveniently divided into two types. The first is *model building* and the second is *pattern detection*. In model building, one seeks to summarize (large parts of) the data in a convenient form. Model building is a familiar exercise, especially to statisticians, and many of the issues in data mining modeling are the same as those in statistics. Differences do arise, however, due to the sizes of the data sets involved, and some of these are discussed below. In pattern detection on the other hand, one seeks anomalies in a data set. Although there are subdisciplines of statistics devoted to this aim (**outlier detection**-, *scan statistics*, and, especially in the behavioral sciences, **configural frequency analysis**-, are examples), in general, far less attention has been devoted to it in the past, at least in statistics. There are probably sound historical reasons for this: many pattern detection problems depend on having a large data set available, and this is a relatively recent development. One might characterize these two rather complementary aspects of data mining as being, on the one hand, like coal mining or oil recovery, where one is extracting and refining large masses of material (this is the modeling aspect), and, on the other, as being like diamond or gold mining, where one is seeking the occasional gem or nugget from within a mass of dross (this is the pattern detection aspect).

Much of the original motivation for data mining has come from the commercial sector: from the promise that the large databases now collected contain, hidden within them, potential discoveries, which could give an organization a market edge. This would include, for example, a superior partition

of customers into groups for sales purposes, better models for predicting customer behavior, and identification of potential fraudulent transactions. However, the tools are now widely used in scientific problems where sometimes truly vast datasets are collected. Scientific areas, which are using data mining methods, include bioinformatics (genomics, proteomics, microarray data (*see* **Microarrays**), astronomy (with giant star catalogues), and medicine (with things like image analysis, scanning technologies, and direct electronic feeds from intensive care patients). The application of such tools in the behavioral sciences is relatively new, but is growing.

Model Building

There are various possible aims in model building. In particular, one can distinguish between summary and prediction. In the former, one merely seeks to summarize data in a manner which is convenient and accurate, while, in the latter, one has in mind the subsequent use of the model for, for example, predicting possible future outcomes or the values of some variables from others. Furthermore, there are different types of models according to whether it is to be based on an underlying theory or is purely empirical. In all cases, however, the objective is to produce a description, which summarizes the data in a convenient and relatively simple form. It will be apparent from this that models typically decompose the entire data set, or at least large chunks of it, into parts: we may decompose a **time series** into trend and seasonal components using signal processing, a distribution of data points into groups using cluster analysis (*see* **Cluster Analysis: Overview; Hierarchical Clustering**), a related set of variables into cliques in a **graphical model**, and so on.

So far, all of the above applies equally to data mining, statistics, and other data analytic technologies. However, it is clear that fitting a model to a data set describing customer behavior consisting of a billion transaction records, or a data set describing microarray or image data with tens of thousands of variables, will pose very different problems from building one for 10 measurements on each of a hundred subjects. One of the most obvious differences is that significance and hypothesis tests become irrelevant with very large data sets. In conventional statistical modeling (in the frequentist approach, at least),

one evaluates the quality of a model by looking at the probability of obtaining the observed data (or more extreme data) from the putative model. Unfortunately, when very large data sets are involved, this probability will almost always be vanishingly small: even a slight structural difference will translate into many data points, and hence be associated with a very small probability and so high significance. For this reason, measures of model quality other than the conventional statistical ones are widely used. Choice between models is then typically based on the relative size of these measures.

Apart from analytic issues such as the above, there are also more mundane difficulties associated with fitting models to large data sets. With a billion data points, even a simple **scatterplot** can easily reduce to a solid black rectangle: a contour plot is a more useful summary. For such reasons, and also because many of the data sets encountered in data mining involve large numbers of variables, dynamic interactive graphical tools are quite important in certain data mining applications.

Pattern Detection

Whereas models are generally large-scale decompositions of the data, splitting the data into parts, patterns are typically small-scale aspects: in pattern detection, we are interested only in particular small localities of the data, and the rest of the data are irrelevant. Just as there are several aims in model building, so there are several aims in pattern detection.

In *pattern matching*, we are told the structure of the pattern we are seeking, and the aim is to find occurrences of it in the data. For example, we may look for occurrences of particular behavioral sequences when studying group dynamics, or purchasing patterns when studying shopping activities. A classic example of the latter has been given the name *bread dominoes*, though it describes a much more general phenomenon. The name derives from shoppers who normally purchase a particular kind of bread. If their preferred kind is not present, they tend to purchase the most similar kind, and, if that is not present, the next most similar kind, and so on, in a sequence similar to a row of dominoes falling one after the other. Pattern matching has been the focus of considerable research in several areas, especially

genomics, espionage, and text processing. The latter is especially important for the web, where search engines are based on these ideas.

In *supervised pattern detection*, we are told the values of some variables, y , and the aim is to find the values of other variables, x , which are likely to describe data points with the specified y values. For example, we might want to find early childhood characteristics, x , which are more likely to have a high value of a variable y , measuring predisposition to depression.

In *pattern discovery*, the aim is both to characterize and to locate unusual features in the data. We have already mentioned outliers as an example of this: we need to define what we mean by an outlier, as well as test each point to identify those, which are outliers. More generally, we will want to identify those regions of the data space, which are associated with an anomalously high local density of data points. For example, in an EEG trace, we may notice repeated episodes, separated by substantial time intervals, in which *'a brief interval of low voltage fast or desynchronized activity [is] followed by a rhythmic (8–12 Hz) synchronized high amplitude discharge ... The frequency then begins to slow and spikes to clump in clusters, sometimes separated by slow waves ... Finally, the record is dominated by low amplitude delta activity'*. Any signal of a similar length can be encoded so that it corresponds to some point in the data space, and similar signals will correspond to similar points. In particular, this means that whenever a signal similar to that above occurs, it will produce a data point in a specific region of the data space: we will have an anomalously high local density of data points corresponding to such patterns in the trace. In fact, the above quotation is from Toone [8]; it describes the pattern of electrical activity recorded in an EEG trace during a grand mal epileptic seizure.

Pattern discovery is generally a more demanding problem than pattern matching or supervised pattern detection. All three of these have to contend with a potentially massive search space, but, in pattern discovery, one may also be considering a very large number of possible patterns. For this reason, most of the research in the area has focused on developing effective search algorithms. Typically, these use some measure of 'interestingness' of the potential patterns and seek local structures, which maximize this. An important example arises in *association analysis*. This describes the search, in a multivariate categorical data

space, for anomalously high cell frequencies. Often the results are couched in the form of *rules*: ‘If A and B occur, then C is likely to occur’. A classic special case of this is *market basket analysis*, the analysis of supermarket purchasing patterns. Thus, one might discover that people who buy sun-dried tomatoes also have a higher than usual chance of buying balsamic vinegar. Note that, latent behind this procedure, is the idea that, when one discovers such a pattern, one can use it to manipulate the future purchases of customers. This, of course, does not necessarily follow: merely because purchases of sun-dried tomatoes and balsamic vinegar are correlated does not mean that increasing the purchases of one will increase the purchases of the other. On the other hand, sometimes such patterns can be taken advantage of. Hand and Blunt [3] describe how the discovery of patterns revealing surprising local structures in petrol purchases led to the use of free offers to induce people to spend more.

Exhaustive search is completely infeasible, so various forms of constrained search have been developed. A fundamental example is the *a priori algorithm*. This is based on the observation that if the pattern AB occurs too few times to be of interest, then there is no point in counting occurrences of patterns which include AB. They must necessarily occur even less often. In fact, this conceals subtleties: it may be that the frequency which is sufficient to be of interest should vary according to the length of the proposed pattern.

Search for data configurations is one aspect of pattern discovery. The other is inference: is the pattern real or could it have occurred by chance? Since there will be many potential patterns thrown up, the analyst faces a particularly vicious version of the *multiplicity* problem: if each pattern is tested at the 5% level, then a great many ‘false’ patterns (i.e. not reflecting real underlying structure in the distribution) will be flagged; if one controls the overall level of flagging any ‘false’ pattern as real at the 5% level, then the test for each pattern will be very weak. Various strategies have been suggested for tackling this, including the use of false discovery rate now being promoted in the medical statistics literature, and the use of likelihood as a measure of evidence favoring each pattern, rather than formal testing. Empirical Bayesian ideas (see **Bayesian Statistics**) are also used to borrow strength from the large number of similar potential patterns.

The technology of scan statistics has much to offer in this area, although most of its applications to date have been to relatively simple (e.g. mainly one-dimensional) situations.

In general, because the search space and the space of potential patterns are so vast, there will be a tendency to throw up many possible patterns, most of which will be already known or simply uninteresting. One particular study [1] found 20 000 rules and concluded ‘the rules that came out at the top were things that were obvious’.

Data Quality

The issue of data quality is important for all data analytic technologies, but perhaps it is especially so for data mining. One reason is that data mining is typically secondary data analysis. That is, the data will normally have been collected for some purpose other than data mining, and it may not be ideal for mining. For example, details of credit card purchases are collected so that people can be properly billed, and not so that, later, an analyst can pore through these records seeking patterns (or, more immediately, so that an automatic system can examine them for signs of fraud).

All data are potentially subject to distortion, errors, and missing values, and this is probably especially true for large data sets. Various kinds of errors can occur, and a complete taxonomy is probably impossible, though it has been attempted [7]. Important types include the following:

- *Missing data*. Entire records may be missing; for example, if people have a different propensity to enter into a study, so that the study sample is not representative of the overall population. Or individual fields may be missing, so distorting models; for example, in studies of depression, people may be less likely to attend interview sessions when they are having a severe episode (see **Missing Data; Dropouts in Longitudinal Studies; Methods of Analysis**).
- *Measurement error*. This includes ceiling and floor effects, where the ranges of possible scores are artificially truncated.
- *Deliberate distortion*. This, of course, can be a particular problem in the behavioral sciences, perhaps especially when studying sensitive topics such as sexual practices or alcohol

consumption. Sometimes, in such situations, sophisticated data capture methods, such as **randomized response** [9], can be used to tackle it.

Clearly, distorted or corrupted data can lead to difficulties when fitting models. In such cases, the optimal approach is to include a model for the data distortion process. For example, Heckman [6] models both the sample selection process and the target regression relationship. This is difficult enough, but, for pattern discovery, the situation is even more difficult. The objective of pattern discovery is the detection of anomalous structures in the data, and data errors and distortion are likely to introduce anomalies. Indeed, experience suggests that, in addition to patterns being ‘false’, and, in addition to them being uninteresting, obvious, or well known, most of the remainder are due to data distortion of some kind. Hand et al. [4] give several examples.

Traditional approaches to handling data distortion in large data sets derive from work in survey analysis, and include tools such as automatic edit and imputation. These methods essentially try to eliminate the anomalies before fitting a model, and it is not obvious that they are appropriate or relevant when the aim is pattern detection in data mining. In such cases, they are likely to smooth away the very features for which one is searching. Intensive human involvement seems inescapable.

The Process of Data Mining

Data mining, like statistical data analysis, is a cyclical process. For model fitting, one successively fits a model and examines the quality of the fit using various diagnostics, then refines the model in the light of the fit, and so on. For pattern detection, one typically locates possible patterns, and then searches for others in the light of those that have been found. In both cases, it is not a question of ‘mining the data’ and being finished. In a sense, one can never finish mining a data set: there is no limit to the possible questions that could be asked.

Massive data sets are now collected almost routinely. In part, this is a consequence of automatic electronic data capture technologies, and, in part, it is a consequence of massive electronic storage facilities. Moreover, the number of such massive data sets

is increasing dramatically. It is very clear that there exists the potential for great discoveries in these data sets, but it is equally clear that making those discoveries poses great technical problems. Data mining, as a discipline, may suffer from a backlash, as it becomes apparent that the potential will not be achieved as easily as the media hype accompanying its advent may have led us to believe. However, there is no doubt that such a technology will be needed more and more in our increasingly data-dependent world. Data mining will not go away.

General books on data mining, which describe the tools in computational or mathematical detail, include [2], [5], and [10].

de Finetti, Bruno

Born: June 13, 1906, in Innsbruck, Austria.

Died: July 20, 1985, in Rome, Italy.

De Finetti's early education was as a mathematician, graduating from the University of Milan in 1927, and then working as government statistician at the National Institute of Statistics in Rome until 1946. His final move was to the University of Rome first in the Department of Economics, then attached to the School of Probability. A considerable amount of his time was spent undertaking actuarial work, not too surprising given his employment. This added both a sense of time and finality to his views on the nature of probability and risk, and a strong conviction that probability was only meaningful in a human context. According to Lindley [1], de Finetti was fond of saying that 'Probability does not exist', by which he meant that probability cannot be thought of independently of the (human) observer. Jan von Plato's recent history of modern probability theory [3] even compares de Finetti to the eighteenth-century Empiricist philosopher David Hume in that probability is likened to sense data and hence *entirely* dependent on the judgment of the observer. This radical vision was formulated by de Finetti around the late 1920s and early 1930s, appearing in a series of papers listed in von Plato [3, p. 298–300]. The central concept through which this subjective approach was worked out is *exchangeability*, that is, the notion that there exist probabilistically 'equivalent sequences of events' (to quote Savage, [2]), which allowed a somewhat weaker form of statistical independence to be used in a subjective context, although most historians note that the notion of exchangeability was not

discovered by de Finetti[3]. De Finetti also pioneered the use of what some people subsequently referred to as the *scoring rule method* of extracting subjective probabilities. Thus, the generation of personal probabilities and probability distributions was relocated by de Finetti to a gambling setting. This orientation was combined by de Finetti with his notion of exchangeability to argue that people who held coherent views on subjective probability would eventually converge on the same subjective probability values if they were faced with, say, separate sequences from a binomial source with a common probability of success. Although de Finetti came from a rather different mathematical tradition and culture than the Anglo-American one, as Lindley points out [1], his influence on key figures in the Bayesian statistics movement (see **Bayesian Statistics**), including Lindsey himself and the American statistician **Leonard Savage**, was decisive. For instance, on page 4 of the introduction to the latter's best-known book [2], one finds the extent to which de Finetti's notion of subjective probability had become the foundation for Savages's own work. More generally, the post-WWII rise of Bayesian statistics gave an enormous boost to de Finetti's international reputation.

de Moivre, Abraham

Born: May 26, 1667, in Vitry-le-François, France.
Died: November 27, 1754, in London, England.

Abraham de Moivre was born in France in 1667 into a protestant family at a time when being a protestant in France was difficult. He attended a variety of schools, but in 1685, when Louis XIV revoked the Edict of Nantes, he was imprisoned for a time and then emigrated to England, where he remained for the rest of his life.

In England, de Moivre made his living as a tutor of mathematics. Soon after his arrival, he met Halley and Newton, and was heavily influenced by both of them. He soon mastered Newton's *Principia*, which was no mean feat, and Halley arranged for his first paper in mathematics to be read before the Royal Society in 1695. In 1697, he was made a fellow of the Society.

De Moivre's most important work was in the theory of probability and analytic geometry. He published his *The Doctrine of Chance: A method of calculating the probabilities of events in play* in 1718, and it was revised and republished several times during his life. He published *Miscellanea Analytica* in

1730, and in that work, he developed Stirling's formula to derive the normal distribution (*see Catalogue of Probability Density Functions*) as an approximation to the binomial. (The original discovery was de Moivre's, though he later credited Stirling, who provided a later simplification.) The normal distribution is one of the critical foundations of modern statistical theory, and its use as an approximation to the binomial is still an important contribution. In developing this approximation, de Moivre had to make use of the standard deviation, though he did not provide it with a name.

Despite de Moivre's eminence as a mathematician, he was never able to obtain a university chair, primarily owing to that fact that he was a foreigner. Even his friends Halley and Newton were not sufficiently influential in supporting his application. As a result, he remained throughout his life a private tutor of mathematics, and died in poverty in 1754.

Decision Making Strategies

Representations of Decision Problems

Decision making is a form of problem solving in which the need to choose among alternative courses of action is the focus of the problem and not merely part of the journey towards its solution. For example, if a student had offers of places on two or more university courses, a decision problem has to be solved. The goal-state of such a problem is usually ill-defined and often a matter of personal preference. At least four types of preferential decision have been defined and studied: multiattribute, risky, sequential and dynamic decisions. Table 1 illustrates a typical multiattribute decision dilemma for a student choosing a course of study: should she choose

Business Studies, which is more relevant to her future career, or Psychology, which she expects to be more interesting? The central issue in multiattribute decision making is how to resolve such conflicts. Table 1 represents this dilemma as a decision matrix of *alternatives* (different courses) varying on several *attributes* (relevance to future career, interest, and so on).

A second important type of decision involves risk or uncertainty. Figure 1 illustrates some of the risky aspects of our student's decision problem represented as a decision tree. If she aspired to graduate level employment after her course, then the safe option would be Business Studies if it led to a job at that level for certain. In comparison, the risky option would be Psychology if that resulted in a only a one-third chance of her target job as a graduate psychologist, but a two-thirds chance of a nongraduate level post which would be a particularly bad outcome for her. Should she take the risk, or opt for

Table 1 Conflicts in course decisions represented as a multiattribute choice

Course	Course attribute			Utility
	Career relevance	Interest of content	Quality of teaching	
Social Anthropology	3	6	8	102
Psychology	5	7	5	105
Business Studies	8	4	4	108
Attribute importance	8	5	6	

Figure 1 Risk or uncertainty represented as a decision tree

the safer course in terms of future employment? That is the typical risky decision dilemma. Decision making where outcome probabilities are known, such as in a game of roulette, are conventionally described as decision under risk. However, decision making where outcome probabilities are unknown, and the stated probabilities represent subjective estimates, as in our example, are known as decision under uncertainty [6, 20].

The other types of decision making (sequential and dynamic) involve situations where people's decisions are dependent on previous decisions they have made. This entry will only consider strategies for multiattribute and risky decision making, for reasons of space. For the same reason, the entry is specifically concerned with evaluative choice rather than evaluative judgment. There is a subtle difference between the two. Evaluative *judgments*, as opposed to decisions, are made when a person is asked to evaluate decision alternatives separately rather than choosing one of them. In consumer contexts, for example, people might be asked to say what they might be willing to pay for an item. A substantial body of research has demonstrated that people apply different strategies in evaluative judgment as opposed to evaluative decision tasks [13, 14, 22]. For example, there is evidence that an anchoring-and-adjustment heuristic is often applied to judgments of the prices of consumer items, but not to choices between them [3].

Two Theoretical Frameworks: Structural Models and Process Descriptions

Two major traditions that have shaped contemporary psychological theories of decision making are utility theory, which aims to predict decision behavior, and the information processing approach, which models underlying cognitive processes. It is assumed in the former that the goal of the rational decision maker is to maximize utility or expected utility. Specific variants of utility theory have been proposed as structural models to describe and predict decision behavior (see entry on utility theory). Such models are not strictly decision strategies, since they do not necessarily correspond to the mental processes underlying decisions. Nevertheless, they can be interpreted as strategies, as discussed below.

Cognitive, or information processing approaches to the study of decision making began to emerge

in the early sixties. Herbert Simon [12] argued that human information processing capacities limit the rationality of decision making in important ways. He believed that utility maximization is beyond cognitive limitations in all but the simplest environments. His *bounded rationality* model assumed that people construct simplified mental representations of decision problems, use simple decision strategies (or heuristics), and often have the goal of making a satisfactory, rather than an optimal, decision. Since Simon's seminal work, much research has adopted his bounded rationality perspective to develop process models describing mental representations, decision strategies and goals. Payne, Bettman, and Johnson [10, p. 9] defined a decision strategy as 'a sequence of mental and effector (actions on the environment) operations used to transform an initial state of knowledge into a final state of knowledge where the decision maker views the particular decision problem as solved'. Process models can be categorized as either single or multistage. Single-stage models describe decision strategies in terms of single sequences of elementary information processing operators (eips) that lead to a decision, whereas multistage models describe sequences of eips that form interacting components of more complex strategies [2].

A Taxonomy of Decision Strategies to Resolve Multiattribute Conflicts

Compensatory Strategies: Additive Utility

Decision strategies can be classified as either compensatory or noncompensatory. The former involve trade-offs between the advantages and disadvantages of the various choice alternatives available, whereas noncompensatory strategies do not. Utility models can be recast within an information processing framework as compensatory decision strategies appropriate for certain contexts. Consider the student's dilemma over which course to choose, illustrated in Table 1. The example assumes a short list of three courses: Social Anthropology, Psychology, and Business Studies. It assumes also that the three most important attributes to the student are the interest of the subject, the quality of teaching, and the relevance of the course to her future career. She has been gathering information about these courses and her assessments are shown in the decision matrix on nine-point scales, where 1 = very poor and 9 = excellent.

In addition, the decision will depend on the relative importance of these attributes to the student: Which is more important, career-relevance or interest? Are they both equally important? The answer will be different for different people.

Utility theorists have proposed a rational strategy to resolve the student's dilemma which takes attribute importance into account. Multiattribute utility theory (MAUT) assumes that each attribute has an *importance weight*, represented in the bottom row of the decision matrix in the table on a nine-point scale (9 = most important). According to MAUT, the utility of each alternative is calculated by adding the utilities of each aspect multiplied by its importance weight [15]. This weighting mechanism ensures that a less important attribute makes a smaller contribution to the overall utility of the alternative than a more important one. For example, utility (psychology) = $(8 \times 5) + (5 \times 7) + (6 \times 5) = 105$ units. Here, the interest value has made a smaller contribution than career relevance, even though the course was rated high in interest value. However, for this student, career relevance is more important, so it contributes more to overall utility. This is a compensatory strategy, since positively evaluated aspects, such as the career-relevance of the Business Studies course, compensate for its less attractive attributes.

Noncompensatory Strategies: Satisficing

Even with our simplified example in Table 1, nine items of information plus three attribute importance weights must be considered. Most real-life decisions involve many more attributes and alternatives and we have limited time and cognitive capacity to cope with all the information we receive. A range of decision strategies we might use in different contexts has been identified. Beach and Mitchel [1] argued that the cognitive effort required to execute a strategy is one of the main determinants of whether it is selected. Building on this, Payne, Bettman, and Johnson [10] developed the more precise *effort-accuracy* framework, which assumes that people select strategies adaptively, weighing the accuracy of a strategy against the cognitive effort it would involve in a given decision context.

One of the earliest noncompensatory strategies to be proposed was Simon's *satisficing principle*:

choose the first alternative, that is at least satisfactory on all important attributes. This saves time and effort because only part of the available information is processed and all that is required is a simple comparison of each aspect with an acceptability criterion. In our example, (Table 1), one could work through each alternative, row by row, perhaps starting at the top. Suppose a rating of 5 was considered satisfactory. Working from left to right across the matrix, the first alternative, Social Anthropology, could be rejected on career-relevance and the other two aspects would not need to be examined. The second alternative would be selected because it passes satisficing tests on all three attributes and consequently, the third alternative would not be considered at all. In this example, satisficing leads to a decision after processing less than half the available information and the conflict across attributes is avoided rather than resolved. Although such a choice process may be good enough in some contexts, satisficing often fails to produce the best decision: the gain in reduced effort is at the expense of a loss of 'accuracy', as Payne et al. argue.

Direction of Processing: Attribute-based or Alternative-based

Amos Tversky [18] proposed two alternative decision strategies to explain how evaluative decisions can violate one of the basic principles of rationality, *transitivity of preference*. Intransitive preference occurs when someone prefers A to B, B to C, but C to A. (A preference for a Psychology over a Business Studies course, Business Studies over Anthropology, but Anthropology over Psychology, would clearly need to be sorted out). Tversky observed similar intransitive cycles of preference with risky decisions, and explained them in terms of attribute-based processing. This is in contrast to alternative-based processing strategies, such as additive utility and satisficing, in which each alternative is processed one at a time. In an attribute-based strategy, alternatives are initially compared on some or all of their important attributes. In Tversky's, *additive difference* strategy, alternatives are compared systematically, two at a time, on each attribute. The differences between them are added together in a compensatory manner, to arrive at an evaluation as to which is the best. For example, in Table 1, the differences between Business Studies and Psychology on career relevance and interest would cancel

out, and the small difference in quality of teaching would tip the balance in favor of Psychology. Tversky showed that intransitive preference could occur if the evaluations of differences were nonlinear ([18], see also [11]).

A noncompensatory attribute-based strategy could also account for intransitive preferences. In a *lexicographic* strategy, the decision maker orders the attributes by importance and chooses the best alternative on the most important attribute (for our hypothetical student, Business Studies is chosen because career-relevance is the most important attribute). If there is a tie on the first attribute, the second attribute is processed in the same way. The process stops as soon as a clear favorite on an attribute is identified. This requires less cognitive effort because usually information on several attributes is not processed (it is noncompensatory since trade-offs are not involved). Tversky argued that if preferences on any attribute form a semi-order, involving intransitive indifference, as opposed to a full rank-order, then intransitivity could result. This is because small differences on a more important attribute may be ignored, with the choice being based on less important attributes, whereas large differences would produce decisions based on more important attributes. He termed this the *lexicographic semi-order* strategy.

Other important attribute-based strategies include dominance testing [9] and elimination by aspects [19]. With respect to the former, one alternative is said to dominate another if it is at least as good as the other on all attributes and strictly better on at least one of them. In such a case there is no conflict to resolve and the rational decision strategy is obvious: choose the dominant alternative. From a cognitive and a rational perspective it would seem sensible to test for dominance initially, before engaging in deeper processing involving substantially more cognitive effort. There is a lot of empirical evidence that people do this. Turning to the elimination-by-aspects strategy, this is similar to satisficing, except that evaluation is attribute-based. Starting with the most important, alternatives are evaluated on each attribute in turn. Initially, those not passing a satisficing test on the most important attribute are eliminated. This process is repeated with the remaining alternatives on the next most important attribute, and so on. Ideally, the process stops when only one alternative remains. Unfortunately, as is the case for most

noncompensatory strategies, the process can fail to resolve a decision problem, either because all alternatives are eliminated, or more than one remain.

Two Stage and Multistage Strategies

It has been found that with complex choices, involving perhaps dozens of alternatives, several decision strategies are often used in combination. For example, all alternatives might initially be screened using the satisficing principle to produce a short-list. Additional screening could apply dominance testing to remove all dominated alternatives, thereby shortening the short-list still further. Following this, a variety of strategies could be employed to evaluate the short-listed alternatives more thoroughly, such as the *additive equal weight* heuristic. In this strategy, the utilities of attribute values are combined additively in a similar manner to MAUT but without importance weights, which are assumed to be equal. Job selection procedures based on equal opportunity principles are often explicitly structured in this way, to make the selection process transparent. Applicants can be given a clear explanation as to why they were selected, short-listed or rejected, and selection panels can justify their decisions to those to whom they are accountable. Beach and his colleagues have developed image theory [1], which assumes a two-stage decision process similar to that described above, that is, a screening stage involving noncompensatory strategies, followed by a more thorough evaluation involving the selection of appropriate compensatory strategies. Other multistage process models describe rather more complex combinations of problem structuring operations and strategies [9, 16, 17].

Strategies for Decisions Involving Risk and Uncertainty

All the strategies discussed so far can be applied to decisions involving risk and uncertainty, if the outcomes and probabilities of the decision tree illustrated in Figure 1 are construed as attributes. However, various specific strategies have been proposed that recognize probability as being fundamentally different to other attributes. The most influential structural models to predict decisions under risk are variants of the subjectively expected utility (SEU) model,

which assume that outcome probabilities are transformed into weights of the subjective values of outcomes. For example, sign and rank dependent models such as prospect theory [4] and cumulative prospect theory [21]. In addition to compensatory strategies derived from SEU, various noncompensatory strategies have been suggested for decision under risk. These include the minimax strategy: choose the alternative with the lowest maximum possible loss. In Figure 1 this would lead to the selection of the alternative with the certain outcome, however attractive the possible gain of the other option might be.

Current Issues

It is important to distinguish between strategies for preferential as opposed to judgmental decisions. In the latter, a choice has to be made concerning whether A or B is closer to some criterion state of the world, present or future (e.g., which has the greater population, Paris or London?). Decision strategies for judgmental choice are discussed in the entry on fast and frugal heuristics. Preferential choice, as defined earlier, is fundamentally different since there is no real world 'best' state of the world against which the accuracy of a decision can be measured. Consequently, decision strategies for preferential choice, though superficially similar, are often profoundly different. In particular, preferential choice often involves some slow and costly, rather than fast and frugal thinking. Certainly, research within the naturalistic decision making framework [7] has identified several fast and frugal decision heuristic used to make preferential decisions (*see* **Heuristics: Fast and Frugal**). For example, the lexicographic strategy described earlier is essentially the same as the fast and frugal 'take the best' heuristic. Similarly, the recognition-primed decisions identified by Klein and his colleagues [5] have the same characteristics, and it has been found that people often switch to strategies that use less information under time pressure [8]. However, evidence related to multistage process theory points to a rather more complex picture. Especially when important decisions are involved, people spend considerable effort seeking and evaluating as much information as possible in order to clearly differentiate the best alternative from the others [16, 17]. One of the main challenges for future research is to model such multistage

decision strategies and validate them at the individual level.

Deductive Reasoning and Statistical Inference

Let us begin by differentiating between *probabilistic* and *statistical* inference. The former is the process of inferring probabilistic statements from other probabilistic statements and is entirely deductive in nature. For example, from $P(h) = 0.5$, $P(e|h) = 0.1$ and $P(e) = 0.2$ one can use Bayes theorem (see **Bayesian Belief Networks**) to infer, with absolute certainty, that $P(h|e) = P(h)P(e|h)/P(e) = 0.5 \times 0.1/0.2 = 0.25$.

Probabilistic inference is thus a subcategory of deductive inference. Statistical inference, in contrast, is the process of inferring general hypotheses about the world from particular observations (see **Classical Statistical Inference: Practice versus Presentation**). Such hypotheses cannot be held with certainty: from the observation of a hundred white swans we might infer that all swans are white, but we cannot do so with certainty. It is tempting to assert that from a hundred white swans we can at least infer either that *probably* all swans are white, or infer the statistical hypothesis that the next observed swan *probably* will be white. However, even these probabilistic options do not hold, as pointed out by the great empiricist philosopher David Hume (1711–76):

... all our experimental conclusions proceed upon the supposition, that the future will be conformable to the past. To endeavour, therefore, the proof of this last supposition by probable arguments, or arguments regarding existence, must be evidently going in a circle, and taking that for granted, which is the very point in question. [5, p. 35–36]

This is Hume's infamous *Problem of Induction* (although Hume did not use the word 'induction' in this context). Any hypothesis worth its salt will make predictions about future observations, but its success on past observations does not *on its own* guarantee successful future prediction. What is more, any claim concerning mere probabilities of various future events also make an unjustified claim that there is some connection between past and future.

The rest of this entry will consider two opposing ways out of this conundrum: the Bayesian approach and the Classical approach. In both cases, the connections with deductive inference will be emphasized.

The Bayesian approach evades the problem of induction by replacing statistical inference by probabilistic inference, which is deductive. To see how this is possible, let us consider a routine case of statistical inference, which will serve as a running example throughout: estimating an unknown probability (p) from a sequence (e) containing r 'successes' and $n - r$ 'failures'. So p might be the unknown probability that a particular coin lands heads, and e might be a sequence of n tosses of that coin, r of which land heads. No matter how large n is, there remains the possibility that the sample mean (r/n) is arbitrarily far from p . It follows that inferring that $p = r/n$ is nondeductive. More interestingly, if $0 < \epsilon < 1$, we cannot even deduce that $|p - r/n| < \epsilon$. If the coin tosses are somehow known to be *independent*, then the Weak **Law of Large Numbers** does at least gives us that $P(|p - r/n| < \epsilon) \rightarrow 1$ as $n \rightarrow \infty$. However, even in this case there is the underlying assumption that each coin toss is a so-called 'identical trial' governed by a fixed unknown probability p . Clearly, such trials are not 'identical' since different results occur. What is really being assumed here is that each coin toss is generated by a fixed set of 'generating conditions' [8] or, as Hacking would have it, a single 'chance set-up' [3]. A satisfactory account of just what is fixed in a given chance set-up and what may vary is still lacking.

The Bayesian approach avoids these difficulties by taking as given a *prior distribution* $f(p)$ over possible values of p (see **Bayesian Statistics**). It also assumes, in common with the Classical approach, that the *likelihood* $f(e|p)$ is given. Since $f(p, e) = f(p)f(e|p)$ this amounts to assuming that the joint distribution $f(p, e)$ is known. All that is then required is to compute the *posterior distribution* $f(p|e)$ (see **Bayesian Statistics**) and this is an entirely deductive process. How successful is this 'deductivization' of statistical inference? What has in fact happened is that any nondeductive inferences have been shoved to the beginning and to the end of the process of statistical inference.

In the beginning is the prior, whose derivation we will now consider. It is not possible to adopt a particular prior distribution by simply observing it to be the case, since, like all probability distributions, it is not directly observable. It is often argued, however, that, at least in some cases, it is possible to infer the true prior. Suppose we had absolutely no knowledge about p , then (one version of) the *Principle of*

2 Deductive Reasoning and Statistical Inference

Indifference permits us to infer that $f(p) = 1$, so that the prior is uniform and $P(a \leq p \leq b) = b - a$ for any a, b such that $0 \leq a \leq b \leq 1$. However, if we are indifferent about p , then surely we should be indifferent about p^2 also. Applying the Principle of Indifference to p^2 yields the prior $f'(p^2) = 1$ so that $P'(a \leq p^2 \leq b) = b - a$. But it then follows that $f'(p) = 1/(2\sqrt{p})$ and $P'(a \leq p \leq b) = \sqrt{b} - \sqrt{a}$. We have ‘logically inferred’ two inconsistent priors. Where the prior is over a single variable, it is possible to avoid this sort of inconsistency by adopting not a uniform distribution but Jeffreys’ noninformative distribution [2, p. 53]. However, when extended for multi-parameter distributions Jeffreys’ distributions are more problematic.

None of the vast literature attempting to rescue the Principle of Indifference from problems such as these is successful because the fundamental problem with the Principle is that it fallaciously claims to generate knowledge (in the form of a prior probability distribution) from ignorance. As Keynes memorably noted:

No other formula in the alchemy of logic has exerted more astonishing powers. For it has established the existence of God from total ignorance, and it has measured with numerical precision the probability that the sun will rise tomorrow. [6, p. 89], quoted in [4, p. 45]

Prior distributions can, in fact, only be deduced from other distributions. If the coin being tossed were selected at random from a set of coins all with *known* probabilities for heads, then a prior over possible values of p can easily be deduced. In such cases, a Bayesian approach is entirely uncontroversial. Classical statisticians will happily use this prior and any observed coin tosses to compute a posterior, because this prior is ‘objective’ (although, in truth, it is only as objective as the probabilities from which it was deduced). In any case, such cases are rare and rest on the optimistic assumption that we somehow know certain probabilities ahead of time. In most cases, the formulation of the prior is a mathematical incarnation of exogenously given *assumptions* about the likely whereabouts of p . If we adopt it as the ‘true’ prior, this amounts to positing these assumptions to be true: a nondeductive step. If we put it forward as merely an expression of our prior beliefs, this introduces an element of subjectivity – it is this to which the Classical view most strongly objects.

Consider now the end result of Bayesian inference: the posterior distribution. A pure Bayesian approach views the posterior as the end result of Bayesian inference:

Finally, never forget that the goal of Bayesian computation is not the posterior mode, not the posterior mean, but a representation of the entire *distribution*, or summaries of that distribution such as 95% intervals for estimands of interest [2, p. 301] (*italics in the original*)

However, the posterior is often used in a semi-Bayesian manner to compute a point estimate of p – the mean of the posterior is a favourite choice. But, as with all point estimates, acting as if some estimated value were the true value is highly nondeductive.

To sum up the principal objections to the Bayesian approach: these are that it simply does not tell us (a) what the right prior is and (b) what to do with the posterior. But as Howson and Urbach point out, much the same criticism can be made of deductive inference:

Deductive logic is the theory (though it might be more accurate to say ‘theories’) of deductively valid inferences from premisses whose truth-values are exogenously given. Inductive logic – which is how we regard subjective Bayesian theory – is the theory of inference from some exogenously given data and prior distribution of belief to a posterior distribution. . . . neither logic allows freedom to individual discretion: both are quite *impersonal* and objective. [4, p. 289–90]

The Classical approach to statistical inference is closely tied to the doctrine of *falsificationism*, which asserts that only statements that can be refuted by data are scientific. Note that the refutation of a scientific hypothesis (‘all swans are white’) by a single counterexample (‘there is a black swan’) is entirely deductive. Statistical statements are not falsifiable. For example, a heavy preponderance of observed tails is logically consistent with the hypothesis of a fair coin ($p = 0.5$). However, such an event is at least *improbable* if $p = 0.5$. The basic form of Classical statistical inference is to infer that a statistical hypothesis (the ‘null’ hypothesis) is refuted if we observe data that is sufficiently improbable (5% is a favourite level) on the assumption that the null hypothesis is true. In this case, the null hypothesis is regarded as ‘practically refuted’.

It is important to realize that, in the Classical view, improbable data does not make the null hypothesis

improbable. There is no probability attached to the truth of the hypothesis, since this is only possible in the Bayesian view. (We will assume throughout that we are not considering those rare cases where there exist the so-called ‘objective’ priors.) What then does it mean, on the Classical view, for a null hypothesis to be rejected by improbable data? Popper justified such a rejection on the grounds that it amounted to a ‘methodological decision to regard highly improbable events as ruled out – as prohibited’ [7, p. 191]. Such a decision amounts to adopting the nondeductive inference rule $P(e) < \epsilon \vdash \neg e$, for some sufficiently small ϵ . In English, this inference rule says: ‘From $P(e) < \epsilon$ infer that e is not the case’. With this nondeductive rule it follows that if h_0 is the null hypothesis and $h_0 \vdash P(e) < \epsilon$, then the observation of e falsifies h_0 in the normal way. A problem with this approach (due to Fisher [1]) concerns the choice of e . For example, suppose the following sequence of 10 coin tosses were observed $e = H, H, T, H, H, H, H, H, H, T$. If h_0 states that the coin is fair, then $h_0 \vdash P(e) = (1/2)^{10} < 0.001$. It would be absurd to reject h_0 on this basis, since any sequence of 10 coin tosses is equally improbable. This shows that care must be taken with the word ‘improbable’: with a large enough space of possible outcomes and a distribution that is not too skewed, then something improbable is bound to happen. If we could sample a point from a continuous distribution (such as the Normal distribution), then an event of probability zero would be guaranteed to occur!

Since e has been observed, we have also observed the events $e' = 'r = 8'$ and $e'' = 'r \geq 8'$. Events such as e'' are of the sort normally used in statistical testing; they assert that a *test statistic* (r) has been found to lie in a *critical region* (≥ 8). $h_0 \vdash P(e'') = 5.47\%$ (to 3 significant figures), so if we choose to test h_0 with e'' as opposed to e , h_0 is not rejected at significance level 5%, although it would, had we chosen 6%. e'' is a more sensible choice than e but there is no justified way of choosing the ‘right’ combination of test statistic and critical region.

In the modern (Neyman–Pearson) version of the Classical approach (see **Neyman–Pearson Inference**) a null hypothesis is compared to competing, alternative hypotheses. For example, suppose there were only one competing hypothesis h_1 , then h_0 would be rejected if $P(e|h_0)/P(e|h_1) \leq k$, where k is determined by the desired significance level. This turns out to solve the problem of choosing

e , but at the expense of a further move away from falsificationism. In the standard falsificationist approach, a black swan refutes ‘all swans are white’ *irrespective* of any other competing hypotheses.

Having dealt with these somewhat technical matters let us return to the deeper question of how to interpret the rejection of a hypothesis at significance level, say, 5%. Clearly, this is not straight logical refutation, nor (since it is non-Bayesian) does it even say anything about the probability that the hypothesis is false. In the literature, the nearest we get to an explanation is that one can *act as if the hypothesis were refuted*. This is generally justified on the grounds that such a decision will only rarely be mistaken: if we repeated the experiment many times, producing varying data due to sampling variation, and applied the same significance test then the hypothesis would not be erroneously rejected too often. But, in fact, it is only possible to infer that *probably* erroneous rejection would not occur often: it is possible (albeit unlikely) to have erroneous rejection every time. Also note that such a justification appeals to what *would* (or more properly *probably would*) happen if imaginary experiments were conducted. This is in sharp contrast to standard falsificationism, which, along with the Bayesian view, makes use only of the data we actually have; not any imaginary data. Another, more practical, problem is that rejected hypotheses cannot be resurrected if strongly supportive data is collected later on, or if other additional information is found. This problem is not present in the Bayesian case since new information can be combined with an ‘old’ posterior to produce a ‘new’ posterior, using Bayes theorem as normal. Finally, notice that confidence is not invested in any particular hypothesis rejection, but on the *process* that leads to rejection. Separating out confidence in the process of inference from confidence in the results of inference marks out Classical statistical inference from both Bayesian inference and deductive inference.

To finish this section on Classical statistical inference note that the basic inferential features of hypothesis testing also apply to Classical estimation of parameters. The standard Classical approach is to use an estimator – a function mapping the data to an estimate of the unknown parameter. For example, to estimate a probability p the proportion of successes r/n is used. If our data were e above, then the estimate for p would be $8/10 = 0.8$. Since we cannot ask questions about the likely accuracy of any particular

4 Deductive Reasoning and Statistical Inference

estimate, the Classical focus is on the *distribution* of estimates produced by a fixed estimator determined by the distribution of the data. An analysis of this distribution leads to **confidence intervals**. For example, we might have a 95% confidence interval of the form $(\hat{p} - \epsilon, \hat{p} + \epsilon)$, where $\hat{p}$ is the estimate. It is important to realize that such a confidence interval does not mean that the true value p lies within the interval $(\hat{p} - \epsilon, \hat{p} + \epsilon)$ with probability 95%, since this would amount to treating p as a random variable. See the entry on confidence intervals for further details.

DeFries–Fulker Analysis

DeFries–Fulker, or DF, analysis [5] refers traditionally to a class of regression models that can be used to provide estimates of the fundamental behavioral genetic constructs **heritability** (h^2) and shared or common environment (c^2) (e.g., [1–3], [7], and [9]) (see **ACE Model**). Initially, two regression models were proposed. The basic model provided effect sizes of h^2 and c^2 on the basis of the individual differences in continuously measured traits. The critical addition of the DF approach, however, was to provide an augmented regression model that provided alternative measures of heritability and shared environment, specific to the extremes in the distribution. The conceptual advance was to provide measurable indicators of extreme group membership (i.e., elevated or diminished scores on a trait) that could be used in modeling heritability and shared environment. This approach offered an alternative to the more traditional biometrical liability model that utilizes statistical transformations of categorical indicators of familial association for diagnoses (e.g., twin concordance rates) (see **Twin Designs**) to yield quantitative genetic parameters on a hypothetical (rather than measured) continuum of liability to disease. The parameters from the two types of regression models used in DF analysis could then be compared to determine if the effect sizes differed for individual differences versus extreme scores, providing one empirical method for assessing if the etiology of the extremes was due in part to unique influences (either genetic or environmental) that are not influential for individual differences.

The basic DF model predicts one sibling's phenotype from the cosibling's as follows:

$$SP_1 = b_0 + b_1 SP_2 + b_2 R + b_3 R \times SP_2 + e \quad (1)$$

The dependent variable is sibling 1's phenotype (SP_1), which is a score on a continuously distributed trait. The independent variables are: (a) the second sibling's phenotype (SP_2); (b) the sibling pair's coefficient of genetic relatedness (R), which reflects the usual coding based on average genetic resemblance for additive traits (e.g., 1 for monozygotic twin, 0.5 for dizygotic twins and full siblings, 0.25 for half-siblings, and 0 for biologically unrelated siblings); and (c) the interaction between the second

sibling's score and the coefficient of genetic relatedness ($SP_2 \times R$). The intercept (b_0) and an error term (e) are also included.

The unstandardized β -weight on the SP_2 variable (b_1) estimates shared environment variance (c^2). The unstandardized β -weight on the interaction term (b_3) estimates heritability (h^2). For these DF analyses, all pairs are double-entered with adjustment for the standard errors of the parameter estimates (which are increased by a multiplicative constant because a standard error is based on the square root of the sample size). It should be noted that this regression model provides a method for conducting biometrical analyses that does not require specialized software and is quite flexible. For example, this basic model can be extended to examine other relevant variables (such as environmental factors) that may serve as moderators of both genetic and environmental influences (e.g., [10]).

Analyses of the extremes require two modifications to this basic model. First, probands are identified, typically as those individuals exceeding a preselected cutoff score in the distribution. Once identified, the regression model is modified to predict cosibling scores as a function of proband score and genetic relatedness. As described by DeFries and Fulker [2, 3], dropping the interaction term from the basic model, when applied to the restricted proband sample and their cosiblings, provides estimates of group heritability (h_g^2) via the unstandardized β -weight on the genetic relatedness (R) variable (b_2) and group-shared environmental influence (c_g^2) via the unstandardized β -weight on the proband phenotype (P) variable (b_1), provided that raw scores are transformed prior to analyses:

$$S = b_0 + b_1 P + b_2 R + e \quad (2)$$

Conceptually, the model analyzes **regression toward the mean** in the cosibling's score as a function of genetic relatedness [7]; heritability is implied by the extent to which such regression is conditional on genetic relatedness (with regression toward the mean increasing with decreasing genetic similarity), and shared environmental effects are suggested by the extent to which there is only partial regression toward the mean (i.e., higher than average cosibling scores), not conditional on genetic relatedness. If both siblings in a pair exceed the cutoff, one is randomly assigned as proband and the other as cosibling, although the double-entry method may also be used, along

with variations in the computation of group-shared environment [4]. This method may be used with both selected and unselected samples and is assumed to be robust to violations of normality in the distribution.

After determining the effect sizes of heritability and shared environment from both the basic and the augmented model, the individual difference and group parameters may be compared by contrasting confidence intervals for each. For example, it has been demonstrated that shared environmental influences are notable for elevated levels of depressive symptoms in adolescence but not for the full range of individual differences (e.g., [4] and [8]).

A model-fitting implementation of the DF method has been introduced, which preserves the function of the regression approach but allows for particular advantages [6]. Fundamental advances in this implementation include the analysis of pairs rather than individuals (eliminating the need for double entry of twin pairs and requisite correction of standard error terms) and the facility to include opposite-sex pairs in a sex-limited analysis. As described in detail in Purcell and Sham [6], the fundamental analytic strategy remains the same, as each observation (i.e., pair) contains a zygosity coefficient, continuous trait score for each member of the pair, and proband status for each member of the pair (i.e., a dummy variable indicating if they have exceeded a particular cutoff). Other details of the analytic procedure can be found in Purcell and Sham [6], including a script for conducting this type of analysis in the statistical program MX.

Demand Characteristics

It was as early as 1933 when Saul Rosenzweig [4] expressed his presumption that unverifiable factors may distort the research results of a psychological experiment. This formed the prelude to Martin T. Orne's first description of the demand characteristics of the experimental situation as 'the totality of cues which convey an experimental hypothesis to the subject' [1, p. 779]. He gave this definition at the symposium of the American Psychological Association in 1959 [3].

Demand characteristics come into being when research data are collected through the exchange of information between human participants, that is, between the researcher or the experimenter on the one hand, and the respondent or the experimental subject on the other hand. The respondents are aware of the fact that they are being observed and know that they are expected to show a particular research behavior. In situations like these, the researcher has no total control over the indications regarding the objectives or hypotheses introduced by either himself or the context.

This complex of unintended or unverified indications that make the respondent think he is able to guess the hypotheses or objectives of the researcher is referred to as the demand characteristics of the research situation.

This obscure tangle of indications is formed by, amongst other things, the data that the respondent had learnt about the research and the researcher prior to the research; the experiences of the respondent as respondent; the expectations and convictions of the respondent regarding the research itself; the setting where the research is conducted; and the manner of measuring.

Demand characteristics elicit answers from the respondents that the researcher can neither verify nor anticipate. Not every respondent reacts in the same way to the research hypotheses and questions he presupposes. Respondents take on different roles [5]. A good respondent will try to support the presumed research hypotheses or questions. He or she will want to meet the researcher part of the way. The behavior of many volunteering respondents is that of a 'good' respondent. The negativist respondent will answer to the research questions in such a manner that the research is obstructed and hindered. In the

interpretation of the effects observed, demand characteristics are responsible for errors of inference or artifacts. The changes in the dependent variables are not so much caused by the independent variables as by a particular disturbing factor, namely, the reaction of the respondents to the demand characteristics of the research. Rosnow [5] calls these factors systematic errors. They are mostly an implicit threat to the 'construct validity' and the **external validity** if the research is conducted from postpositivistic paradigms. However, if the research is conducted from interpretative paradigms, they constitute a threat to the 'credibility' and 'transferability'.

It is the task of the researcher to find out whether there are any demand characteristics present in the research that have significantly influenced respondent behavior.

Orne [1, 2] has developed three 'quasi-control' strategies to detect demand characteristics in the research.

A first possible strategy is the 'postexperimental interview'. The respondents' emotions, perceptions, and thoughts with regard to the research and the researcher are assessed by means of questionnaires. This is done in order to find out whether the respondent had some understanding of the research hypotheses. Another technique is 'preinquiry' or 'nonexperiment'. The experimental procedures are carefully explained to prospective respondents. Subsequently, they are asked to react as if they had actively participated in the planned experiment. If the same data are obtained with these respondents as with the actual participants, there may have been a possible influence of demand characteristics.

In a third strategy, that of 'the use of simulators', the researcher works with respondents acting as if they have been part of the experiment, whereas this is evidently not the case. Now, it is for the researcher to tell the genuine respondents from those who are simulating. If he is unable to do so, certain data in the case may be the result of demand characteristics.

The 'quasi-control' strategies may help the researcher to detect the presence of demand characteristics. The actual bias, however, cannot be proved. Some scientists hope to neutralize this form of bias by applying techniques to reduce the systematic errors caused by the demand characteristics to unsystematic errors, if possible.

2 Demand Characteristics

Robson [3] proposes to restrict the interaction between the researcher and the respondent as much as possible. In his view, this can be done by making use of taped instruction or of the automated presentation of material.

Deming, Edwards William

Born: October 14, 1900, in Iowa.

Died: December 20, 1993, in Washington.

William Deming's career was as colorful and varied as it was long. Thus, he began his working life as a mathematical physicist, but then switched to the role of consultant and propagandist to the newly emerging field of American industrial and business statistics, a field that has produced much of modern statistical theory and practice. This change had been prefigured in his earliest publication titled *Statistical Adjustment of Data* [1], first published in 1938 but available in a paperback edition as late as 1985. The book represented 16 years of work both as teacher and consultant and researcher, and is mainly concerned with integrating all the various flavors of curve fitting, where such curves provide the replacement for or adjustment of the original data. Thus, adjustment here means the choice of a representative number or function for a sample. The main criterion for this selection is that the number supplies the information for *action*. There is, in other words, a strong operational and instrumental force behind Deming's views on statistics. The motivation for his work was, therefore, highly practical and as a consequence led him to work in both academic and business and Government settings: He was, for example, employed by the American Department of Agriculture and then was with the Bureau of the Census, for nearly 20 years in total. During this period, he also introduced American statisticians to such British and European luminaries as **Ronald Fisher** and **Jerzy Neyman**, both of whom he had studied with in the United Kingdom in 1936. He had also collected and edited a volume of the latter's unpublished lectures and conference contributions.

After what appears to be an idyllic but hard early life on a farm in Wyoming, Deming had graduated from the University of Wyoming in 1921 as an electrical engineer. His subsequent degrees included a Masters from the University of Colorado in 1924 (he had taught at the Colorado School of Mines for 2 years prior to this degree) and a Ph.D. in mathematical physics from Yale in 1928. In 1927, Deming began his long association with Government

until 1946 when he was appointed to a Chair in the Graduate School of Business Administration at the University of New York (he also held the position of 'Distinguished Lecturer' in Management at Columbia University from 1986). Here, his career as international consultant and management *guru* flourished (but not curiously in postwar America), with extensive tours in South America, Europe, and Asia, particularly in Japan where he had been adviser on sampling techniques to the Supreme Command of the Allied Powers in Tokyo as early as 1947. His long-term espousal of quality control methods, particularly those invented by Shewhart, together with his extensive practical experience of sampling in various industrial settings (see [2]) and his enormous capacity for hard work meant that he was a natural to help Japan become an industrial world leader from the 1960s onward. It also appears that the Japanese businessmen who visited Deming in America were equally impressed by him as a person, for example, that he lived in an unpretentious house in Washington, DC, and that he had clearly not attempted to make any serious money from his efforts [3]. According to Paton, therefore, many leading Japanese businessmen and politicians viewed Deming as a 'virtual god' [4]. Indeed, the somewhat religious aspect of his work was revealed during his many Four Day Seminars on quality control and management, where the famous Fourteen Points to successful management had to be accepted with minimal dissent by the participants (see [4], for an eyewitness account of a seminar given in 1992, when Deming had only a year to live). Only after American industry had been seriously challenged by Japan in the late 1970s and early 1980s had there arisen a call to adopt Deming's winning formula, a neglect that he seemed never to have really forgotten or forgiven.

Design Effects

Introduction

Survey researchers can only be assured of obtaining a representative sample of subjects when a probability sampling plan is used [9]. Simple random sampling (SRS) in which all eligible study subjects have the same probability of being selected, is the most basic of such plans (*see Randomization; Survey Sampling Procedures*). However, this design is usually recommended only when one has little additional information beyond a list of eligible subjects. More sophisticated sampling plans tend to be used in most actual surveys.

Consider, for example, the multistage, stratified, cluster sample used by the National Crime Victimization Survey (NCVS) [9]. This survey estimates the amount of crime in the United States, supplementing crime statistics compiled by the Federal Bureau of Investigation (FBI), known to be limited to crimes reported to law enforcement agencies. According to the NCVS sampling plan, random samples of census enumeration districts are selected from within strata defined on the basis of geographic location, demographic data, and rates of reported crime. This sampling plan increases the precision with which crime statistics are estimated, while ensuring national and local representation. Clusters of households are then sampled from within enumeration districts and finally all household members at least 12 years of age are asked about their experience as victims of crime over the past six months. The selection of subjects from within household clusters is an effective and cost-efficient method of identifying eligible subjects across a wide age range.

Sample size estimation for sampling plans typical of that used in the NCVS can be quite complicated. A method of simplifying calculations is to assume data will be obtained using SRS and then accounting for the use of **stratification** and clustering using design effects. We define this concept in section ‘what is a design effect?’, and demonstrate its role in sample size estimation for a cluster randomized trial in section ‘worked example’. This example also demonstrates that, while design effects were originally defined by Kish [6, 7, 13] in the context of survey sampling, they are in fact much more

broadly applicable. Some related issues are discussed in section ‘discussion’.

What is a Design Effect?

A goal of the NCVS is to estimate p , the proportion of respondents who were victims of crime in the six months prior to being surveyed. The design effect associated with $\hat{p}$ (the estimator of p) in the NCVS is given by

$$deff = \frac{Var_{NCVS}(\hat{p})}{Var_{SRS}(\hat{p})}, \quad (1)$$

where $Var_{NCVS}(\hat{p})$ denotes the variance of $\hat{p}$ obtained using the NCVS sampling plan while $Var_{SRS}(\hat{p})$ denotes the variance of this statistic obtained using SRS. More generally, a design effect is defined as the ratio of the variance of an estimator for a specified sampling plan to the variance of the same estimator for SRS, assuming a fixed overall sample size. In this sense, the design effect measures the statistical efficiency of a selected sampling plan relative to that of SRS.

The selection of subjects from within strata and the use of cluster sampling are often motivated by practical concerns, as is seen in the NCVS. Stratification typically results in gains in statistical efficiency ($deff < 1$) to the extent that selected strata are predictive of the study outcome. In this case, greater precision is secured by obtaining an estimate of variability that is calculated within strata. In the NCVS, FBI crime statistics were used to define strata, a strategy intended to increase the precision of $\hat{p}$. Conversely, cluster sampling typically reduces statistical efficiency ($deff > 1$), since subjects from the same cluster tend to respond more similarly than subjects from different clusters, thus inflating estimates of variance. The competing effects of stratification and cluster sampling combine in the NCVS to provide a design effect for $\hat{p}$ of about two [9], indicating that SRS is twice as efficient as the selected sampling plan. Consequently NCVS investigators would need to enroll twice as many subjects as they would under SRS in order to obtain an equally efficient estimate of p .

Worked Example

Greater insight into the interpretation and calculation of design effects may be obtained by considering a

2 Design Effects

worked example from a school-based smoking prevention trial. As part of the Four Group Comparison Study [10] children were randomly assigned by school to either one of three smoking prevention programs or to a control group. Randomization by school was adopted for this trial since allocation at the individual level would have been impractical and could also have increased the possibility that children in an intervention group could influence the behavior of control group children at the same school.

Unfortunately, the selected programs in this trial proved ineffective in reducing tobacco use among adolescents. However, suppose investigators decided to design a new trial focusing specifically on p , the proportion of children using smokeless tobacco. The corresponding design effect is given by

$$deff = \frac{Var_{SR}(\hat{p})}{Var_{IR}(\hat{p})}, \quad (2)$$

where $\hat{p}$ denotes the sample estimate of p , $Var_{SR}(\hat{p})$ denotes the variance of $\hat{p}$ assuming random assignment by school and $Var_{IR}(\hat{p})$ denotes the variance of $\hat{p}$ assuming individual random assignment. One can show [3] that in this case, $deff \approx 1 + (\bar{m} - 1)\rho$, where $\bar{m}$ denotes the average number of students per school and ρ is the **intraclass correlation** coefficient measuring the similarity in response between any two students in the same school. With the additional assumption that ρ is nonnegative, this parameter may also be interpreted as the proportion of overall variation in response that can be accounted for by between-school variation.

Data are provided in Table 1 for the rates of smokeless tobacco use among the students from the 12 control group schools randomized in the Four Group Comparison Study [3, 10], where the average number of students per school is given by $\bar{m} = 1479/12 = 123.25$. Therefore, the sample estimate of ρ may be calculated [3] as

$$\begin{aligned} \hat{\rho} &= 1 - \frac{\sum_{j=1}^k m_j \hat{p}_j (1 - \hat{p}_j)}{k(\bar{m} - 1) \hat{p} (1 - \hat{p})} \\ &= 1 - \frac{[152 \times 0.0132(1 - 0.0132)] + \dots + [125 \times 0.1280(1 - 0.1280)]}{12(123.25 - 1)0.0615(1 - 0.0615)} \\ &= 0.013324, \end{aligned} \quad (3)$$

where $\hat{p}_j = y_j/m_j$ and $\hat{p} = Y/M = 91/1479 = 0.0615$ denote the prevalence of smokeless tobacco

Table 1 Number and proportion of children who report using smokeless tobacco after 2 years of follow-up in each of 12 schools [3, 10]

j	y_j	m_j	$\hat{p}_j$
1	2	152	0.0132
2	3	174	0.0172
3	1	55	0.0182
4	3	74	0.0405
5	5	103	0.0485
6	12	207	0.0580
7	7	104	0.0673
8	7	102	0.0686
9	6	83	0.0723
10	6	75	0.0800
11	23	225	0.1022
$k = 12$	16	125	0.1280
Total	$Y = 91$	$M = 1479$	$\hat{p} = Y/M = 0.0615$

use in the j th school and among all 12 schools, respectively.

The estimated design effect is then seen to be given approximately by

$$1 + (123.25 - 1)0.013 = 2.6, \quad (4)$$

indicating that random assignment by school would require more than twice the number of students as compared to an individually randomized trial having the same power. Note that the design effect is a function of both the degree of intraclass correlation and the average number of students per school, so that even values of $\hat{\rho}$ close to zero can dramatically inflate the required sample size when $\bar{m}$ is large.

Now suppose investigators believe that their new intervention can lower the rate of smokeless tobacco use from six percent to three percent. Then using standard sample size formula for an individually randomized trial [3], approximately 746 students would be required in each of the two groups at a 5% two-sided significance level with 80% power. However, this result needs to be multiplied by $deff = 2.6$, implying that at least 16 schools need to be randomized per intervention group assuming approximately 123 students per school ($746 \times 2.6/123.25 = 15.7$). In practice, investigators should consider a range of plausible values for the design effect as it is frequently estimated with low precision in practice.

Discussion

Trials randomizing schools are an example of a more general class of intervention studies known as cluster randomization trials. The units of randomization in such studies are diverse, ranging from small clusters such as households or families, to entire neighborhoods and communities but also including worksites, hospitals, and medical practices [3]. Cluster randomization has become particularly widespread in the evaluation of nontherapeutic interventions, including lifestyle modification, educational programmes, and innovations in the provision of health care.

We have limited attention here to trials in which clusters are randomly assigned to intervention groups without the benefit of matching or stratification with respect to baseline factors perceived to have prognostic importance. Design effects for these relatively simple designs are analogous to those obtained for surveys involving a one-stage cluster sampling scheme [9]. One distinction is that investigators designing surveys often incorporate finite population correction factors since then clusters are typically selected without replacement [9]. However, such correction factors have very little impact when the selected clusters represent only a small fraction of the target population.

Comparisons of design effects computed across studies have led to some interesting empirical findings. For instance, estimates of design effects often vary less across similar variables or studies than does the estimated variance [1]. This greater 'portability' argues for the use of design effects in place of the variance of a statistic when estimating sample size in practice. Data from cluster randomization trials and from surveys using cluster sampling also reveal that the degree to which responses of cluster members are correlated, and consequently the size of the resulting design effect, will tend to vary as a function of cluster size [3, 5]. Not surprisingly, responses among subjects in smaller clusters (e.g., households) tend to be more highly correlated than responses among subjects in larger clusters (e.g., communities). This is intuitively sensible, since people from the same household tend to be more alike than randomly selected subjects who live in the same city. However, although the magnitude of the intraclass correlation coefficient tends to decline with cluster size, it does so at a relatively slow rate. Thus, design effects of greater magnitude are usually obtained in

studies enrolling large clusters such as communities than in studies randomizing households, even though the value of the intraclass correlation tends to be much greater for the latter.

Our discussion has focused on the application of design effects for sample size estimation when the outcome of interest is binary. However, sample size estimation procedures that incorporate design effects have also been reported for studies having a range of other outcomes (e.g., continuous [3], count [3], time to event [15]) and more generally to allow for covariate adjustment (*see Analysis of Covariance*) [11]. Extensions of these formulae have also been derived for surveys where analyses need to consider the effects of both cluster sampling and weighting to account for unequal selection probabilities [4]. Design effects can furthermore be incorporated to compare costs of different sampling plans, as discussed by Kish [6] and Connelly [2].

The application of design effects is not limited to sample size estimation and to comparing the efficiency of competing sampling plans. They can also be used to adjust standard test statistics for features of the sampling plan [3, 9, 12] although these procedures become more approximate when covariate adjustment is required [9, 11, 14]. In this case it is preferable to use more sophisticated regression models requiring software capable of simultaneously accounting for weighting, stratification, and clustering (see, e.g. [8]).

Confidentiality concerns may impose limits on the amount of information that can be released about the design of a survey. For example, the public-use data from the NCVS did not include information about who belonged to the same cluster [9]. Data analysts will then have to approximate the effects of clustering using average design effects [14] or, in their absence, exploit the availability of external data to assign an *a priori* value for the design effect. Given the sensitivity of statistical inferences to the assigned values of the design effect, we would discourage this latter practice unless very reliable and representative external data are available.

Development of Statistical Theory in the 20th Century

At the beginning of the twentieth century, the dominant figures in statistics were **Francis Galton (1822–1911)**, **Karl Pearson (1857–1936)**, and **George Udny Yule (1871–1951)**. Galton, whose mathematics was rudimentary but whose insight was truly remarkable, had developed the theory of regression and, subsequently, of correlation. Karl Pearson was an enthusiastic follower of Galton who wished to apply statistical methods to substantial quantities of real data. In doing so, he developed various families of statistical distributions, which he tried to fit to his data. This led naturally to the search for a method of estimating parameters and hence to his ‘method of moments’ and, subsequently, to the need for a measure of ‘goodness of fit’ and hence to the development of the chi-squared test (*see Goodness of Fit for Categorical Variables*). His methods were unsuitable for small samples, and it was ‘Student’ (a pen name for **William Sealy Gosset, 1876–1937**) who began to develop small-sample methods with his statistic, subsequently modified to give what is now known as Student’s t .

The towering genius of twentieth-century statistics was **Ronald Aylmer Fisher (1890–1962)** who further developed the theory of small samples, giving rigorous proofs of the distributions of χ^2 , t , and Fisher’s z (which is equivalent to F). He further established the principle of maximum likelihood (*see Maximum Likelihood Estimation*) as a method of estimation, which proved far more successful than the method of moments. Unfortunately, both Karl Pearson and Fisher were of a quarrelsome nature and they fell out over various issues, including the distribution of the correlation coefficient, the correct number of degrees of freedom in a 2×2 contingency table and methods of estimation.

Fisher worked from 1919 to 1933 at the Rothamsted agricultural research station, which led to his development of most of the present-day techniques of the design and analysis of experiments. Subsequently, he was Galton Professor of Eugenics at University College, London, and Arthur Professor of Genetics

at Cambridge, and he always regarded himself primarily as a scientist. His books [1, 2, 4] (especially the first two) were immensely influential, but can be difficult to follow because proofs and mathematical details are omitted.

Fisher’s use of significance tests is well illustrated by his discussion in Chapter III of [4] of the observation that the star β Capricorni has five close neighbors among 1500 bright stars for which he has data. Assuming that the stars are randomly distributed about the celestial sphere, Fisher shows that this event has a probability of 1 in 33 000. He concludes that *either* an exceptionally rare event has occurred *or* the theory of random distribution is not true. In Fisher’s view, scientific theories should be tested in this way, and, while they may, at a certain P value (1 in 33 000 in the example) be rejected, they can never be finally accepted.

Fisher’s theory of inference was largely based on his ‘fiducial argument’ (expounded, e.g., in [4]), which depends on the existence of ‘pivotal quantities’ whose distribution does not depend on unknown parameters. For example, if $x_1, \dots, x_n$ are independently normally distributed with mean μ and variance σ^2 and their sample mean and standard deviation are m and s respectively, then $t = (m - \mu)/(s/\sqrt{n})$ is a pivotal quantity with Student’s t distribution on $n - 1$ degrees of freedom, whatever μ and σ may be. Fisher then deduced that μ had a fiducial distribution, which was that of $m - (s/\sqrt{n})t$ (where, in finding the distribution, m and s are thought of as constants). Often, but not invariably, the fiducial distribution is the same as that given by the method of inverse probability, which is essentially the Bayesian argument discussed below using uniform prior distributions. A particularly controversial case is the Behrens–Fisher problem, in which the means μ_1 and μ_2 of two samples from independent normal distributions are to be compared. Then, if $\delta = \mu_1 - \mu_2$ and $d = m_1 - m_2$ the distribution of $\delta - d$ is that of $(s_1/\sqrt{n_1})t_1 - (s_2/\sqrt{n_2})t_2$, where t_1 and t_2 are independent variates with t distributions. In this case (and others), the probability given by the fiducial argument is not that with which rejection takes place in repeated samples if the theory were true. Although this fact ‘caused him no surprise’ [3, p. 96], it is generally regarded as a defect of the fiducial argument.

In the early 1930s, **Jerzy Neyman (1894–1981)** and Karl Pearson’s son **Egon Sharpe Pearson (1895–1980)** developed their theory of hypothesis

testing (see **Neyman–Pearson Inference**). In the simplest case, we are interested in knowing whether an unknown parameter θ takes the value θ_0 or the value θ_1 . The first possibility is referred to as the null hypothesis H_0 and the second as the alternative hypothesis H_1 . They argue that if we are to collect data whose distribution depends on the value of θ , then we should decide on a ‘rejection region’ R , which is such that we reject the null hypothesis if and only if the observations fall in the rejection region. Naturally, we want to minimize the probability $\alpha = P(R|\theta_0)$ of rejecting the null hypothesis when it is true (an ‘error of the first kind’), whereas we want to maximize the probability $1 - \beta = P(R|\theta_1)$ of rejecting it when it is false (thus avoiding an ‘error of the second kind’). Since increasing R decreases β but increases α , a compromise is necessary. Neyman and Pearson accordingly recommended restricting attention to tests for which α was less than some preassigned value called the *size* (for example 5%) and then choosing among such regions one with a maximum value of the ‘power’ $1 - \beta$. Fisher, however, firmly rebutted the view that the purpose of a test of significance was to decide between two or more hypotheses.

Neyman and Pearson went on to develop a theory of ‘**confidence intervals**’. This can be exemplified by the case of a sample of independently normally distributed random variables (as above), when they argued that if the absolute value of a t statistic on $n - 1$ degrees of freedom is less than $t_{n-1,0.95}$ with 95% probability, then the random interval $(m - st_{n-1,0.95}, m + st_{n-1,0.95})$ will contain the true, unknown value μ of the mean with probability 0.95. Incautious users of the method are inclined to speak as if the value μ were random and lay within that interval with 95% probability, but from the Neyman–Pearson standpoint, this is unacceptable, although under certain circumstances, it may be acceptable to Bayesians as discussed below.

Later in the twentieth century, the Bayesian viewpoint gained adherents (see **Bayesian Statistics**). While there were precursors, the most influential early proponents were **Bruno de Finetti** (1906–1985) and **Leonard Jimmie Savage** (1917–1971). Conceptually, Bayesian methodology is simple. It relies on Bayes theorem, that $P(H_i|E) \propto P(H_i)P(E|H_i)$, where the H_i constitute a set of possible hypotheses and E a body of evidence. In the

case where the ‘prior probabilities’ $P(H_i)$ are all equal, this is essentially equivalent to the method of ‘inverse probability’, which was popular at the start of the twentieth century. Thus, if we assume that $x_1, \dots, x_n$ are independently normally distributed with unknown mean μ and known variance σ^2 , then assuming that all values of μ are equally likely *a priori*, it is easy to deduce that *a posteriori* the distribution of μ is normal with mean m (the sample mean) and variance σ^2 . In the case where σ^2 is unknown, another conventional choice of prior beliefs for σ^2 , this time uniform in its logarithm, leads to the t Test, which Student and others had found by classical methods. Nevertheless, particularly in the continuous case, there are considerable difficulties in taking the standard conventional choices of prior, and these difficulties are much worse in several dimensions. Controversy over Bayesian methods has centered mainly on the choice of prior probabilities, and while there have been attempts to find an objective choice for prior probabilities (see, e.g., [5, Section 3.10]), it is now common to accept that the prior probabilities are chosen subjectively. This has led some statisticians and scientists to reject Bayesian methods out of hand. However, with the growth of **Markov Chain Monte Carlo Methods**, which have made Bayesian methods simple to use and made some previously intractable problems amenable to solution, they are now gaining in popularity.

For some purposes, formal statistical theory has declined in importance with the growth of ‘**Exploratory Data Analysis**’ as advocated by **John W Tukey (1915–2000)** and of modern graphical methods as developed by workers such as William S. Cleveland, (1943), but for many problems, the debate about the foundations of statistical inference remains lively and relevant.

Differential Item Functioning

Differential item functioning (DIF) occurs when individuals at the same level on the trait(s) or construct(s) being assessed but from different subpopulations have unequal probabilities of attaining a given score on the item. The critical element in the definition of DIF is that individuals from the different subpopulations are matched on the traits of interest before their responses are compared. Performance differences that remain after matching on the relevant variables must be because of group differences on an additional trait being tapped by the item. Note that while unidimensionality of the test is commonly assumed in practice, DIF can occur in multidimensional tests whenever a test item taps an unintended trait on which groups differ [16].

By its definition, DIF is distinguished from impact, which is defined as a simple mean difference in performance on a given item for the subpopulations of interest. Impact occurs whenever there is a mean difference between subpopulations on the trait. Impact is easily observed and understood by nonpsychometricians, and as a result has become the legal basis for exclusion of items in some high-stakes tests; psychometricians repudiate such practices because of the failure of nonpsychometricians to take into account valid group differences. A further distinction is made between DIF and bias. While DIF was once known as ‘item bias’, modern psychometric thought distinguishes the concepts; the term ‘bias’ carries an evaluative component not contained in the detection of differential performance on the item. Holland and Wainer [10] define item bias as ‘an informed judgment about an item that takes into account the purpose of the test, the relevant experiences of certain subgroups of examinees taking it, and statistical information about the item.’ Hence, evidence of DIF is necessary but not sufficient for the conclusion of bias.

In DIF studies, two groups are usually compared at a time, one of which is denoted the reference group; the other, the focal group. Typically, the majority group (e.g., Whites, males) is taken as the reference group and the focal group is the minority group of interest.

Two types of DIF are commonly differentiated: uniform and nonuniform [17]. Uniform DIF is present when the difference between (or ratio of) the probabilities of a given response in the reference and focal groups is constant across all levels of the trait; that is, the item is uniformly more difficult for one group than the other across the trait continuum. Nonuniform DIF is present when the direction of differences in performance varies or even changes direction in different regions of the trait continuum; that is, the item is differentially discriminating. Hanson [8] makes further distinctions between uniform, unidirectional, and parallel DIF.

The study of DIF began in the 1960s [1] and has been vigorously pursued in the intervening years. The large majority of research on DIF methods has focused on dichotomously scored items; only since the early 1990s has much attention been given to methods for detecting DIF in polytomously scored items. Early ‘item bias’ methods were based on item-by-group interactions and failed to adequately disentangle DIF from impact. These early methods have been reviewed and their shortcomings identified by a number of authors [26]; none of these methods is currently in wide use and hence are not described here.

As noted above, the central element in the definition of DIF is that the comparison of reference and focal groups be conditional on trait level. The manner in which that conditioning is operationalized provides a convenient basis for classifying DIF methods in current use. Millsap and Everson [18] distinguish methods based on unobserved conditional invariance (UCI) from those based on observed conditional invariance (OCI). UCI methods condition on model-based estimates of the trait, while OCI methods condition on an observed proxy for the trait, typically total test score. The primary UCI methods are those based on item response theory (*see Item Response Theory (IRT) Models for Polytomous Response Data; Item Response Theory (IRT) Models for Rating Scale Data*).

Item response theory (IRT) provides a natural framework for defining and investigating DIF. Item response models specify the probability of a given response to an item as a function of the unobservable trait underlying performance and characteristics of the item [7]. If item response functions (IRFs) for a specific item differ for subpopulations of interest, this indicates that examinees at the same trait value do not

2 Differential Item Functioning

have the same probability of the response, and hence that DIF is present. Thus, IRT methods for detecting DIF involve comparison of IRFs. Approaches to quantifying this comparison are based on comparison of item parameters, comparison of item characteristic curves, or comparison of model fit. Millsap and Everson [18] provide a comprehensive review of IRT DIF methods that encompasses the majority of research done on these methods to date.

Lord [15] proposed a statistic, often referred to as D^2 , to test for equality of the vectors of item parameters for the two groups. The test statistic requires the vector of item parameter estimates and the variance-covariance matrices of the estimates in each group and has an approximate chi-square distribution with degrees of freedom equal to the number of item parameters compared. Lord [15] notes that the chi-square distribution is asymptotic and strictly holds only when the true theta values are known. A practical problem with the D^2 statistic is that the variance-covariance matrix of the item parameter estimates is often not well-estimated [28].

Differences between item characteristic functions have been quantified by computing the area between the curves. Bounded and unbounded area statistics have been developed. Bounded statistics are necessary when the c-parameters for the two groups differ, as in this case, the area between item characteristic curves is infinite. Kim and Cohen [12] developed a formula for bounded area, but no standard error or test statistic has been derived. Raju [21] provided a formula for computing the area between IRFs when the c-parameters are equal. Raju [22] further provided a standard error formula and derived an approximately normal test statistic.

Likelihood ratio statistics can be used to compare the fit of a model based on equality constraints on parameters across all items with that of a model in which the item parameters for the studied item are estimated separately within groups. Thissen et al. [28] described a likelihood ratio test statistic proportional to the difference in the log likelihoods under the constrained and unconstrained models. The likelihood ratio and D^2 statistics are asymptotically equivalent; Thissen et al. [28] argue that the likelihood ratio test may be more useful in practice because it does not require computation of the variance-covariance matrix of the parameter estimates. However, the likelihood ratio procedure requires fitting a

separate model for each item in the test; by comparison, the D^2 statistic requires only one calibration per group.

Limitations of IRT methods include the necessity for large sample sizes in order to obtain accurate parameter estimates, the requirement of model-data fit prior to any investigation of DIF, and the additional requirement that the parameter estimates for the two groups be on a common scale before comparison. Each of these issues has been subject to a great deal of research in its own right. IRT methods for detecting DIF remain current and are considered the theoretical ideal that other methods approximate; however, for the reasons given above, they are not as widely used as more easily computed methods based on OCI.

A variety of OCI-based methods have been proposed. All use total score in place of the latent variable. Problems with the use of total score as a conditioning variable have been noted by many authors [19]. A fundamental issue is that the total score may be contaminated by the presence of DIF in some of the items. ‘Purification’ procedures are routinely used to ameliorate this problem; these procedures involve an initial DIF analysis to identify DIF items, removal of these items from the total score, and recomputation of the DIF statistics using the purified score as the conditioning variable [9, 17].

Logistic regression procedures [23, 27] most closely approximate IRT methods by using an observed score in place of the **latent variable** and in essence fitting a two-parameter model in each group. Swaminathan and Rogers [27] reparameterized to produce an overall model, incorporating parameters for score, group, and a score-by-group interaction. An overall test for the presence of DIF is obtained by simultaneously testing the hypotheses that the group and interaction parameters differ from zero, using a chi-square statistic with two degrees of freedom. Separate one degree of freedom tests (or z tests) for nonuniform and uniform DIF are possible by testing hypotheses about the interaction and group parameters, respectively. Zumbo [29] suggested an R-square **effect size measure** for use with the logistic regression procedure. The logistic regression procedure is a generalization of the procedure based on the **loglinear model** proposed by Mellenbergh [17]; the latter treats total score as a categorical variable. The advantages of the logistic regression procedure over other OCI methods are

its generality and its flexibility in allowing multiple conditioning variables.

The standardization procedure of Dorans and Kulick [6] also approximates IRT procedures by comparing empirical item characteristic curves, using total score on the test as the proxy for the latent trait. Unlike the logistic regression procedure, the standardization index treats observed score as a categorical variable; differences between the probability of a correct response (in the case of dichotomously scored items) are computed at each score level, weighted by the proportion of focal group members at that score level, and summed to provide an index of uniform DIF known as the *standardized P-DIF statistic*. Dorans and Holland [5] provide standard errors for the standardization index but no test of significance. Because it requires very large sample sizes to obtain stable estimates of the item characteristic curves, the standardization index is not widely used; it is used largely by Educational Testing Service (ETS) as a descriptive measure for DIF in conjunction with the **Mantel–Haenszel (MH)** procedure introduced by Holland and Thayer [9].

The MH procedure is the most widely known of the OCI methods. The procedure for dichotomously scored items is based on contingency tables of item response (right/wrong) by group membership (reference/focal) at each observed score level. The null hypothesis tested under the MH procedure is that the ratio of the **odds** for success in the reference versus focal groups is equal to one at all score levels. The alternative hypothesis is that the **odds ratio** is a constant, denoted by α . This alternative hypothesis represents uniform DIF; the procedure is not designed to detect nonuniform DIF. The test statistic has an approximate chi-square distribution with one degree of freedom. Holland and Thayer [9] note that this test is the uniformly most powerful (*see Power*) unbiased test of the null hypothesis against the specified alternative. The common odds ratio, α , provides a measure of effect size for DIF. Holland and Thayer [9] transformed this parameter to the ETS delta scale so that it can be interpreted as the constant difference in difficulty of the item between reference and focal groups across score levels. Holland and Thayer [9] note that the MH test statistic is very similar to the statistic given by Mellenbergh [17] for testing the hypothesis of uniform DIF using the log-linear model. Swaminathan and Rogers [27] showed equivalence between the MH and logistic regression

procedures if the logistic model is reexpressed in logit form, the total score treated as categorical, and the interaction term omitted. In this case, the group parameter is equal to $\log \alpha$. The primary advantages of the MH procedure are its ease of calculation and interpretable effect size measure.
